An understanding of genome function within the context of human cells requires new methodology. This article describes comparative approaches that are used for genomes and genes in situ. However, the major focus of the article is on differential display (DD) and subtractive hybridization (SH) because these two methods are most accessible to a large number of researchers. The basic principles of these methods are described along with some fundamental reminders about the important factors that must be kept in mind for successful experiments.

1 INTRODUCTION

There are an increasing number of genomic sequences becoming available. Within the next 5 years even the human genome sequence should be completed. Understanding the meaning of these DNA sequences will take much more work and involve many comparative experiments.

In the past, gene function was defined by comparing a cell containing a specific mutation with a cell that did not have the mutation. Mutations are also used quite effectively for dissecting biochemical mechanisms and pathways. The power of using mutations lies in the fact that a very well defined change is being studied. In the past, most research was confined to model organisms with well-developed genetic systems that allowed gene manipulations. This type of approach is quite useful for experimental organisms that have well-developed genetic systems which allow gene manipulation. It is quite clear that these types of experiments will continue in the future. However, it is also clear that we need to understand gene function in complex organisms where gene manipulation is not possible or easily done.

Comparative studies in the complex genomes are difficult. For instance, it is estimated that there may be over 100 000 genes in the human genome. Of course, there are many naturally occurring mutations that aid geneticists and other researchers to understand disease and other natural processes. However, even putting aside the ethics of manipulating human genomes for experimental purposes, humans are not good experimental organisms because their life span is too long. Hence, it is quite clear that comparative methods focused on complex organisms with long life spans must be independent of gene manipulations. Furthermore, even with ''good'' experimental organisms, the number of known genes and interactions are too great to be dissected by past methods using conventional recombinant DNA methods. In such experiments, genes are cloned, sequenced, modified and studied in detail out of their native genomic environments.

A large number of methods and variations have been developed for comparing whole genomes and entire repertoires of genes. Most methods can be applied to large and small genomes. The technical difficulty of a particular approach is usually a function of genome size. This article will review genomic comparative techniques, focusing on DD and SH because these methods are most accessible to a large number of researchers.

For simplicity, all calculations done will assume a random DNA sequence composition. However, for many organisms the amount of sequence information available in the databases allows for more accurate calculations of experimental results and for some completely sequenced genomes, a total modeling of the experimental results.

2 OPTIONS FOR COMPARING GENOMES

There are several approaches for comparing, globally, genome structure and function. These studies can be divided into those that compare the primary structure of genomic DNA and those that compare gene expression profiles. It should be noted that gene expression profiling requires quantitative analysis of levels that vary by 10^5-fold. This means that quantitative studies on gene expression are more complicated than direct genome comparisons.

Gene expression profiling is currently most often done at the mRNA level. Such experiments do not provide information about post-transcriptional regulation of gene expression. Two-dimensional gel electrophoresis has been used for some time to establish and compare protein profiles from different samples. Some recent experiments compare mRNA and protein profiles from the same sample. In yeast, Gygi et al.[1] found little correlation between protein and mRNA expression levels. It will be interesting to see what post-transcriptional regulatory mechanisms are uncovered and how these initial observations are extended to other organisms and systems. These types of comparative experiments and protein profiling in general will not be discussed here.

2.1 DNA Fingerprinting Methods

Genomic sequence comparisons between different samples is the only reliable method to detect all differences. Gene expression profiling can be done using DNA sequencing methodology. In these approaches, random cDNAs are sequenced and the frequency of occurrence of specific sequences is recorded in different cells or under different conditions such as disease states. Some have termed this electronic profiling and several successful biotechnology companies specialize in this approach. These types of experiments form the new field of pharmacogenetics. (Pharmacogenetics promises to tailor treatment and medication to individuals.)

A variation on random cDNA sequencing is called serial analysis of gene expression (SAGE).[2] SAGE links short bits of cDNA sequence together in a single sequencing template to increase efficiency of the analysis. Even so, the financial cost of current technology prevents widespread use of large-scale sequencing experiments for global comparative studies.

DNA fingerprint methods have been used to compare both genomic DNA and cDNA sequences. The first method that was developed hybridized a multilocus simple, tandem repeat probe to restriction enzyme cleaved genomic DNA fractionated electrophoretically.[3] Since then a number of easier polymerase chain reaction (PCR) methods have been developed for DNA fingerprinting. In some cases, PCR is used to amplify unique sequences located between primer sequences composed of arbitrary primers (randomly amplified polymerase chain reaction, RAPD).[4,5] In other cases, the primer sequences consist of interspersed repeat sequences, for example Alu sequences in the human genome.[6] The pool of PCR amplified fragments are size fractionated electrophoretically to create a complex DNA fingerprint. The DNA fingerprints of two or more samples are compared to assess the similarity and differences between samples.

DD[7] compares the size distribution pattern of DNA fragments generated from random amplification of two mRNA samples. Here, we will distinguish cDNA differential display (cDD) from genomic differential display (GDD). A more detailed discussion of these methods is given below.

Methods such as sequencing by hybridization (SBH, also known as DNA chip arrays)[8,9] replace time-consuming electrophoretic size fractionations with a single-stranded DNA array composed of different sequences. Hybridization of a single-stranded sample to a DNA array produces a DNA fingerprint revealing which array sequences are complementary to a position of the sample DNA. In conventional SBH, the presence but not the location of the sequence is obtained. The sample sequence may be reconstructed from the pattern of short oligonucleotides that hybridize to the template. An alternative method, called positional sequencing by hybridization (PSBH),[10] revealed both the presence and location of the complementary sequence. In this protocol, the array targets are partially double stranded and have a single-stranded end. In this format, the single-stranded end of the target sequence hybridizes to the probe element with stacking interactions from the duplex region insuring a high level of matching bases. The specificity of this hybridization may be increased by adding enzymatic steps, such as a DNA ligation and/or polymerase extension reaction.

In SBH, oligonucleotides are typically immobilized in an array format on a silicon chip to which a labeled template is hybridized. The presence of the template on each array element is scored as positive or negative when conventional radioactive, fluorescent or chemiluminescent labels are used.

Conventional SBH experiments have been severely handicapped by the hybridization of mismatched sequences, especially end mismatches. PSBH reduces the level of mismatches at least 10-fold. Further enhancement may be obtained when SBH experiments are analyzed by mass spectrometry (MS).[11]

MS analysis does not require a label. MS not only detects the presence of a species as do the other detection methods but also provides the mass of the molecule. Since the masses of the bases are known, different

sequence compositions with distinguishable masses may be distinguished when they are hybridized to the same array element. Potentially, MS allows the experimental results to be precisely correlated to DNA sequence(s).

DNA arrays may also be composed of other molecules. For instance, cloned cDNAs,[12,13] or genomic sequences[14] or even uncloned single or pools of genomic restriction fragments[15] may be used as targets.

Comparative genome hybridization (CGH)[16] experiments hybridize pairs of differentially labeled genomic DNA or cDNAs to normal metaphase chromosomes. Usually, one sample is labeled with fluorescein and the second with 4′,6-diamidino-2-phenylindole (DAPI). The samples are mixed together at equimolar ratios. Hybridization to metaphase chromosome means that the DNA probes are sorted to chromosomal regions. The fluorescein/DAPI signal ratio will remain contant unless there is a region that is amplified or deleted in one of the genomic DNA samples. Likewise, when cDNA probes are analyzed, the fluorescein/DAPI signal ratio will remain constant except for those regions where there is a difference in gene expression. CGH provides a low resolution (~10 Mb) genomic localization of differences and does not provide directly the sequence causing the difference. The advantage is that a controlled pairwise comparison is done, providing a much more robust quantitative analysis. The disadvantage is that the complexities of this method do not allow it to be adapted by a large number of laboratories. A similar type of ''two-color'' approach has also been applied to analyzing DNA arrays.[17]

2.1.1 Isolation of DNA Differences Between Samples

All of the experiments discussed above may be classified as DNA fingerprinting methods. These methods present similarities and differences between samples. An alternative to these approaches are methods that provide information only about the differences between samples.

In SH, only ''candidate'' differences are provided to the experimenter. An advantage of the DNA fingerprinting methods are that they can be quantitative and provide ongoing information to the experimenter. An advantage of the SH experiments is that they provide directly the candidate differences between samples. The DNA fingerprinting experiments provide information about differences that then must be isolated for further testing. In both approaches, the first chore of the experimenter is to prove that the indicated differences are real. This will allow the level of false differences between samples (i.e. false positives) to be assessed. The level of false negatives (false similarities) between samples is more difficult to assess. Our own approach to this problem has been to verify our method using a model system where the experimental results can be compared with the theoretical results (see below) and where few, if any, differences should exist between samples.

DD and SH are technically demanding. The key to success lies in understanding the underlying biochemistry and biophysics. The goal of this article is to provide the user with a basic understanding of the principles of these methods and factors that affect reliability. Also discussed are some of the many options and applications.

3 DIFFERENTIAL DISPLAY

3.1 Principles

DD was originally developed by Liang and Pardee[18] as a PCR method for amplifying and labeling subsets of mRNA to identify differences in gene expression. A recent useful collation of a variety of DD articles can be found in Liang and Pardee.[7] The pool of amplified products <500 bp (base pairs) is size-fractionated on a high-resolution DNA sequencing gel. This produces a display consisting of the size-dependent banding pattern of the pool of PCR products. The display produced from two or more samples is compared to identify differences in gene expression patterns.

In the originally described method,[18] the starting material was purified mRNA which is converted to cDNA using conventional methods. Then PCR was used to amplify subsets of the cDNA library. One of the PCR primer pairs was complementary to the polyA tail of eukaryotic mRNA with additional 3′-anchor bases (e.g. $5'T_{11}CA3'$). The use of a homopolymer T primer with a unique dinucleotide 3′-end serves two purposes. First, the unique dinucleotides anchored the primer to the unique genomic sequences adjacent to the 5′-end of the polyA mRNA tail. This insured the polymerase extension reaction initiated at the sequence adjacent to the polyA tail and not randomly within the mRNA polyA tail. The anchor bases also control the complexity of the PCR amplification products. Twelve different dinucleotide (e.g. CA, CT, CG, CC, GA, GT, GG, GC, AA, AT, AG, AC) anchors are needed to amplify all mRNA specifically. In a random sequence, a dinucleotide anchored primer sequence would reduce the number of PCR amplification with a specific dinucleotide anchor products by 1/12.

The second PCR primer was a 10-mer composed of an arbitrary sequence (e.g. Ltk3, CTTGATTGCC). There are 1049 different possible 10-mer combinations and any one 10-mer sequence would be expected to occur once in 10^6 bp. Since an average mRNA is about 10^3 bp in length, a single 10-mer should hybridize to 1 in 10^3 cDNAs.

DD analysis is usually restricted to fragments less than 10^3, hence the number of amplified products should be even less. The arbitrary primers used in these experiments

were chosen after testing to give reproducible and specific amplification products with the polyT anchored primers. Subsequent studies have taken a more critical look at the theoretical distribution of primers so that the speed and efficiency of DD could be maximized.[19]

3.2 Options

3.2.1 Genomic Analysis

Genomic comparisons of simple genomes may be done directly. For instance, it is quite easy using pulsed field gradient (PFG) techniques to compare chromosomal fingerprints of small genomes like bacteria, yeast and protozoan.[20] The resolution of these methods can be improved by establishing fingerprints using restriction enzymes that cleave infrequently and in some cases restriction enzymes that cleave frequently. These types of approaches can be applied to organisms whose genomes range in size up to about 100 million bp. In contrast, the human genome is 1000-fold greater than this. With today's technology it is still impossible to compare directly total human genomes. Instead genome complexity must be reduced.

We[21–25] and others[26–28] have reported on the use of targeting in DD. In this approach, a class of fragments containing a specific sequence (a target sequence) is selected for analysis (see below). In contrast to others, our methods have focused on analyzing selected genomic fragments rather than cDNAs (targeted genomic differential display (TGDD) vs targeted cDNA differential display (TcDD) respectively). The focus on genomic DNA allows for an exact modeling of the expected results using DNA from genomes whose entire sequence is known and was easier to develop as a quantitative method because of the smaller dynamic range requirements (e.g. ~2-fold versus 10^5-fold for genomic vs cDNA studies, respectively).

Two methods for TGDD were established by us.[29] In both methods, oligonucleotides of known sequence are ligated to the ends of genomic restriction fragments. In Method I, there is an initial hybridization – capture step which is used to purify the restriction fragments that contain the target sequence away from the remaining restriction fragments. An immobilized oligonucleotide complementary to the target sequence is used for the hybridization – capture step. Subsequently, the captured fragments are amplified by PCR. A single PCR primer complementary to the adapter sequences ligated onto the ends of the genomic fragments may be used. Alternatively, the adapter primer may be used with a primer complementary to the target sequence. In the former case, sequences from each side of the target are amplified; in the latter case the sequence from only one side of the target is amplified.

Method I eliminates the capture step and uses long (40-mer) adapter primers to enhance self-annealing of the adapter primers, an effect called PCR suppression.[30] In this method, a primer to the target sequence and a short 20-mer primer to the adapter sequence are used. Only fragments that contain a target sequence can be amplified. This version of the method has the advantage that it is easier to perform. Although, the adaption of interspersed repetitive element-bubble PCR[31] with Method I should prevent self-annealing of the adapter sequences,

Targeting has been adapted to cDNA studies (Nguyen et al., unpublished results). In TcDD, the adapter primer was replaced by a primer complementary to the polyA tail.

3.2.2 Targeting

A detailed discussion of targeting issues can be found in Bouchard et al.[29] In brief, it is important to realize that targeting can be done with a simple repeating sequence (the polyA tail of eukaryotic cDNA is one example of this) or more complicated sequence coding for a protein motif, a *cis*-acting sequence such as transcriptional activation signal. The method can analyze the target sequence itself and/or the surrounding sequence depending on the PCR primer that is used. Usually, the target is interspersed throughout the genome. This means that the method samples sequences spread throughout the genome. In some cases the target may be more confined to a specific chromosomal region, for example telomeric sequences. In the case of simple repeating sequences, unique bases added to the 3′- or 5′-end of the primer serves to anchor the primer to the target end and to reduce complexity (see above).

The question of how to design more complex motif primers that target gene families is not yet answered. Most, if not all, gene families consensus sequences were developed comparing amino acid compositions and not DNA sequences. In fact, very little work has been done on characterizing gene families at the DNA sequence level because it is clear that there can be much more variability at the DNA sequence level because of the redundancy of the genetic code. Additionally, different preferential codon usage is observed in different organisms and an emerging complication is that codon usage in a particular species may reflect the expression level of the protein sequence and/or be protein class specific.

3.3 Trouble Shooting

The major problem with DD experiments is the high number of false positives. A suggested way of dealing with this issue is to reconfirm each alleged difference individually by hybridization. This requires that the

DNA fragment be isolated and/or sequenced so that a hybridization probe can be generated.

Our own experience with TGDD has suggested several ways of improving the experimental results. One of the most important factors is to analyze high-resolution Gaussian-like distributions of the fragment size fractionations. In most DD experiments, the sample is radioactively labeled and the fractionation results recorded by exposure of the polyacrylamide gel to film to produce a banding pattern. Although this type of analysis is useful, especially if the focus is kept on the differential presence of very dark bands, a much more realistic pattern of intensity changes is obtained when higher resolution data are collected in real time on an automated DNA sequencing instrument.

Our extensive characterization of the factors that influence the reliability of DD has led us to the conclusion that the most important aspect is to match the starting DNA concentrations. There are several reasons for doing this; in particular, the occurrence of unequal amplification of the PCR product during the late cycles. This problem is likely related to the specific sequence that needs to be amplified. For example, although the human genome is 60% A + T, usually equal amounts of the trinucleotide precursors are added to the PCR. This may mean that in each cycle of PCR there is a 20% difference in the use of trinucleotide precursors dATP and TTP vs dCTP and dGTP. Furthermore, the Michaels constant (K_m) of each trinucleotide is different. Hence, the cycle at which precursors become limiting will differ. Of course, this is only a theoretical consideration. The real inequities must be based on the base composition of each fragment in the amplified pools. Another cause of unequal amplification may be the rapid annealing of high concentration PCR products, which would then prevent the subsequent annealing or extension of primers. These considerations emphasize the importance of using samples with matched DNA concentrations and a low number of PCR cycles.

Another consideration in any experiment involving nucleic acids, and especially those involving DNA, is the accurate determination of the sample concentration. It is difficult to accurately determine DNA concentrations. In the cell, 90% of the nucleic acid is RNA. This means that the greatest detriment to accurately determining DNA concentration from a cell extract is contaminating RNA sequences. Although it is possible to purify DNA from RNA via density gradient centrifugations, this is not usually done because of the limiting amount of material that is available. RNA or DNA specific dyes can be used but they will bind to the alternative species with less affinity as pointed out by many of the manufacturers. The problem is that the amount of contaminating material is unknown. Hence, it is more useful to be consistent in the manner in which DNA concentrations are determined and correlating this with useful results. In fact, since the entire scientific community has this problem it might be best to try several initial (two-fold variations below and above the target) DNA concentrations. Additionally, one might consider varying the number of PCR cycles by two cycles around the target to minimize the number of experiments needed, especially when starting out.

An important issue that cannot be ignored is the ratio and concentration of the primers in the PCR. For small oligonucleotide primers, the annealing temperature will be concentration dependent in addition to being sequence dependent.[32] Other considerations in these types of multilocus are the frequency of occurrence of particular sequences in the template DNA as well as the sequence conservation. The best way to handle these variables is to determine the best ratio and concentration of primer pairs to use empirically. Typically we titrate multilocus primers against each other in the 0.3 to 2 mM range.

3.4 Applications

There are many applications for DD and an increasing number of publications are appearing using this technology. Most publications focus on cDNA applications. Our own studies using TGDD on closely matched genomes compare the genomes of twins, families and different tissues from the same individual. The goal of these experiments is to determine the effect of genome stability and heritability on phenotype.

4 SUBTRACTIVE HYBRIDIZATION

4.1 Principles of Subtractive Hybridization

The goal of SH experiments is to isolate a target sequence(s) (T) that is present in one sample, called the test DNA (S), and absent in a matched sample, called the driver DNA (D). There are a large number of published protocols. In all cases, a mixture of excess D mixed with S, is denatured and allowed to reanneal. In this reaction there are three single-stranded species which can be distinguished as shown in Figure 1.

The D and S DNAs can form parental homoduplexes or heteroduplexes with complementary strands. All

Figure 1 Single-stranded DNA.

Figure 2 T DNA homoduplexes.

sequences are in common except for the T DNA. The T DNA can only form homoduplexes (Figure 2).

Equation (1) describes the kinetics of double-stranded DNA formation.[32]

$$f_{ds} = \frac{k_2 C_0 t}{1 + k_2 C_0 t} \tag{1}$$

where k_2 is the second-order rate constant, C_0 is the initial concentration of single-stranded DNA segments, and t is time. The fraction of DNA that has formed double strands, f_{ds}, can be calculated from the initial concentration as shown in Equation (2):

$$C_{ds} = f_{ds} C_0 = k_2 C_0^2 t \tag{2}$$

When this equation is applied to SH, two DNA samples must be considered. The first sample contains S- and T-type DNA; the second sample, D, contains only S-type DNA. Since T strands will only form double strands with other T strands the concentration of T : T, denoted C_{Tds}, can be determined from Equation (2). Equation (3) shows:

$$C_{Tds} = \frac{k_2 C_T^2 t}{1 + k_2 C_T t} \tag{3}$$

The formation of S : S, S : D, D : D can be determined by considering first the kinetics of D : D formation and then extracting the amount of S : S formed from the mole fraction of S : S, $X_{S:S}$ (see Equation 4). This can be done under the conditions where the concentration of S is negligible compared to the concentration of D.

$$X_{S:S} = \frac{C_{S1}^2}{C_{D1}^2} \tag{4}$$

where C_{S1} and C_{D1} denote the initial concentrations of S- and D-type strands respectively.

Equation (5) shows

$$(C_{Sds}) = (C_{D1}) \times X_{S:S} = \frac{k_2 C_{D1}^2 t \times C_{S1}^2}{(1 + k_2 C_{D1} t) C_{D1}^2}$$
$$= \frac{k_2 C_{S1}^2 t}{1 + k_2 C_{D1} t} \tag{5}$$

After the hybridization the next step is enrichment by PCR. Only the T : T and S : S strands have matching primers so only those strands will be exponentially amplified. This effectively removes S : D and D : D strands reducing the amount of S contaminants and enriching the amount of T strands. The ratio of enrichment resulting from the first subtraction round is given by Equation (6):

$$E = \frac{(C_{Tds})}{(C_{Sds})} = \frac{(k_2 C_T^2 t)}{(1 + k_2 C_T t)} \times \frac{(1 + k_2 C_{D1} t)}{k_2 C_{S1}^2 t}$$
$$= \frac{(C_T^2) \times (1 + k_2 C_{D1} t)}{(C_{S1}^2) \times (1 + k_2 C_T t)} \tag{6}$$

Since the T and the S strands come from the same genome they have the same concentration. Under this assumption the enrichment effectively simplifies to Equation (7):

$$E = \frac{(C_{Tds})}{(C_{Sds})} = \frac{C_{D1}}{C_T} \tag{7}$$

Therefore the enrichment ratio is increased or the amount of contaminating S strands is decreased simply by using a much higher concentration of D strands relative to T.

4.2 Options

Many variations and ''improvements'' on the SH concept have been published. Despite this, routine success has been elusive, although it is becoming more frequent. The major improvements in the technology included a minimization and simplifying the number of manipulations, use of PCR amplification, and developing more effective protocols through an improved understanding and modeling of the hybridization kinetics of a variety of approaches.

4.2.1 Polymerase Chain Reaction Subtraction

A commercial SH kit sold by Clontech is called ''PCR-Subtraction''. The principles but not the details of this procedure will not be presented here. (Details of this protocol can be found in material available from Clontech.)

This protocol was developed from modeling experiments of a variety of SBH protocols.[33–35] The authors considered several protocols: double-stranded DD and double-stranded SS (+TT); double-stranded DD and complementary single-stranded S (+T); single-stranded D and double-stranded SS (+TT); single-stranded D and complementary single-stranded SS (+TT). The initial modeling experiments focused on cDNAs and a single cycle protocol was developed. This method, called PCR subtraction, allows differential expressed genes to be isolated in a single round of subtraction for complex genomes and genomic differences to be isolated for microorganisms of genomes less than 10 Mb (Figure 3).

Figure 3 PCR subtraction.

In this protocol, first denatured 3 g D and 0.1 g S (+T) DNAs are annealed together in 1.5 L for 20 h at 68 °C. This allows an approximate equalization of the differentially expressed genes in the single-stranded fraction because of the second-order hybridization kinetics of the different cDNA abundance classes. In practice, two simultaneous initial SH reactions are carried out. The only difference in the reactions is that the S DNAs have different adapter sequences ligated onto their 5′-ends. The 5′-ends do not have a ligated adapter sequence because double-stranded unphosphorylated adapters were used. No adapters are ligated onto the D samples. The two reactions are mixed together and added, undenatured, to a new fraction of denatured D. During the second hybridization, the fragments shared between D and S are reduced further. The single-stranded T fragments in the two reactions will now form a TT with different 5′-end sequences. In a subsequent PCR the ends are filled in. Only duplexes with unmatched ends are amplified because the homoduplexes with complementary adapters self-anneal and preventing annealing of the shorter PCR primers, a phenomenon called suppression PCR.[30] This method takes advantage of rapid annealing of T DNA relative to the remaining S DNA in the single-stranded fraction.

4.3 Trouble Shooting

The major nonobvious difficulties in SH experiments, are similar to those encountered in DD experiments. Many of the problems can be alleviated by careful attention to DNA concentrations. However, a major difficulty is the assessment of DNA concentrations that are extremely critical and may best be handled empirically, especially when getting started.

4.4 Applications

There are many applications of SH experiments and progress is being made in identifying cDNAs differentially expressed. The major problems that need to be resolved are how to detect single base pair differences between samples and how to carry out total genomic subtraction experiments. In fact, more complex protocols have been developed using a complex reduction protocol with a gel electrophoresis step called in-gel competitive hybridization (IGCH)[36–38] and/or a preferential PCR amplification step called representational difference analysis (RDA).[39] In IGCH, excess D and T are mixed together, denatured and then fractionated using high-resolution electrophoresis. Individual size fractions are isolated from the gel and allowed to anneal.

5 OTHER CONSIDERATIONS

Most genome comparative experiments are not done on single cells because of the added difficulty of working with small amounts of DNA and in the case of genomic DNA, two molecules. Hence, the results present an average of several and usually, many cells. It is clear that it would be valuable to develop comparative methodology that allows the analysis of single cells. For instance, the analysis of single cells making up a tissue would provide information on the range of changes occurring in a tissue rather than the average of the changes.

There are several methods that can use the PCR to amplify DNA from low copy, including single molecules. One of the first methods was primer extension pre-amplification (PEP).[40] Reasonable success was reported with a primer pool of length $n = 15$, containing every possible 4^{15} primer. The concentration of any unique species is extremely low, but apparently high enough to insure amplification (e.g. 30 cycles) of most (estimated to be ~80%) of the genome after 50 cycles of PCR. A major

problem with this method is the potential for the primers to interact with each other.

An improvement to this method used a chimeric primer, with a variable portion and a conserved portion. This method was called tagged polymerase chain reaction (T-PCR)[41] because genomic fragments were tagged with a common adapter sequence during the PCR. In T-PCR, each primer had a 5′-end with a constant 17 base sequence and a 3′-end with a variable 9 base sequence. The first few rounds of PCR were done with the chimeric primer, then this primer was removed and the remaining PCR cycles were done with a primer solely composed of the constant region located at the ends of the tagged amplified fragments. A number of variations were developed, such as degenerative oligonucleotide-primed polymerase chain reaction (DOP-PCR).[42] Here the primer contains an internal variable portion (9 bases in length), a long 5′ constant region of 13 bases in length and a short 3′ constant region (3 bases in length). Cheung and Nelson[43] demonstrated that, with a slight modification, DOP-PCR could be used to amplify random genetic markers from small amounts of DNA.

6 PERSPECTIVE

Comparative genomics is a rapidly changing field. Perhaps the most important aspect in the application of a specific technology is adaptability. Not only is it important to stay advised of critical improvements in methods and conceptualization that create quantum improvement in the technology, but it is also important to be able to adapt new technologies as they become available.

The question of how one decides on a specific approach is more difficult. DD does not, in general, provide sequences of interest but rather shows you where they are so they may be isolated. DD provides quantitative information on the number and the extent of differences. The end results of an SH experiment are the sequences of interest. However, SH does not provide information about the number or the level of differences.

Technological advances have created more DNA detection systems with more power than ever before. By amplifying the target or its molecular counterpart, the probe, very minute amounts of DNA can be detected or even sequenced. Different technologies give rise to different DNA detection systems. Each system has its merits and limitation. In many applications, detection sensitivity is the parameter of interest. This article first gives an outline of different DNA detection systems and their sensitivities and limits. It then describes how to achieve and prove one-copy sensitivity. Finally, it discusses the testing strategy, supported by statistics to increase detection confidence. Although the limit of detection (LOD) can be improved with better technology and instrument, the highest sensitivity is set by probability laws. To detect one-copy of a DNA molecule, one needs to understand the properties of single.

1 INTRODUCTION

The ability to detect deoxyribonucleic acid (DNA) molecules is crucial to the development of molecular biology and today's many analytical instruments for biological applications. From the beginning of the molecular biology era, the search for better ways to detect DNA has never stopped. Such endeavor has led to enormous advances in our understanding of DNA – the basic building block of life. It was the improvement in X-ray diffraction that generated the crystallographic data for DNA and formed the basis of the classical discovery of the double helix structure by Watson and Crick.[1] It was the DNA polymerase chain terminator sequencing method that allowed us to read the genetic make-up of life and revolutionized the field of automated sequencing.[2] It is the polymerase chain reaction (PCR) that makes DNA detection, cloning and sequencing so easy and so powerful.[3–6]

It used to take days to detect a target DNA by restriction enzyme digestion, gel electrophoresis and Southern blot hybridization.[7] Now this can be done in a matter of hours in a tiny, single tube. The thermally stable *Taq* DNA polymerase isolated from *Thermus aquaticus* can amplify DNA more easily by cycling through the temperatures of denaturing and annealing than billions of *Escherichia coli* bacteria used to do in conventional DNA cloning.

2 CURRENT TECHNOLOGIES OF DNA DETECTION

2.1 Principles

Nucleic acid probes interact with their complementary target sequences mainly through H-bonding. We call such an interaction molecular hybridization. Molecular hybridization between probe and target sequences is the basis for most current technologies of DNA detection. Mass spectrometry (MS), which detects DNA by separating ionized molecules according to their ratios of mass to electric charge, is an exception. There are direct and indirect detection methods. Direct detection usually involves an excessive amount of target DNA and specialized instruments or methods that detect DNA without modifying the original quantity. In many applications, however, the limited amount of target DNA prohibits direct detection. In this case, indirect detection involving either probe or target DNA amplification can be used to enhance the signal of the probe or target.

2.2 Methods, Instrumentation and Applications

DNA can be detected directly by a number of methods and instruments. Using a spectrophotometer with ultraviolet (UV) capability to measure optical absorbance (OD) at 260 nm, it is possible to detect DNA in aqueous solution at a concentration of 250 ng mL^{-1} and above. For accurate measurement, however, a concentration of 1 μg mL^{-1} or higher is preferred. Ethidium bromide (ETBr) forms a noncovalent complex with double-stranded DNA by intercalating between stacked base pairs. Upon UV illumination, the DNA–ETBr complex emits an orange fluorescence which allows the detection of DNA. This is usually used in conjunction with agarose or polyacrylamide gel electrophoresis (PAGE). DNA is first separated based on size by gel electrophoresis, then the DNA in the gel is visualized by staining with ETBr and illuminated with a UV transilluminator. Photographs of stained gels showing DNA bands are often taken with a Polaroid camera. As little as 10 ng of a 300 base pair (bp) DNA can be detected in this way. Using the molecular hybridization technique, one can transfer the DNA bands from agarose gels to a solid membrane and use a DNA as a probe to detect another DNA that has a homologous sequence.[7]

Both DNA and RNA molecules can be detected by molecular hybridization. Nucleic acid samples can also be spotted directly on a solid membrane and such a method is called dot blot or slot blot, depending on the way in which the sample is applied to the membrane. The probe can be labeled radioactively or nonradioactively, providing a means for detection following molecular hybridization. The molecular hybrid is visualized with the aid of an X-ray film when radioactive or chemiluminescence labeling is used, or by colorimetric detection of biotin/alkaline phosphatase–streptavidin conjugate.[8] As little as 10^6 copies of a DNA or RNA sequence can be detected by molecular hybridization methods. Subpicomolar levels of DNA can be detected directly with a mass spectrometer. However, it cannot distinguish a target-specific sequence in a sample containing mixed DNA molecules.

In addition to direct detection of DNA, there are indirect detection methods that involve amplification of either the target DNA or its probe. The most widely used target amplification technology is the PCR.[3–6] It is possible to detect one DNA molecule by PCR amplification.[6] Among a number of probe amplification techniques, the branched deoxyribonucleic acid (bDNA) system is the most successful.[9] It is possible to detect as few as 50 molecules with bDNA technology.[10]

Molecular hybridization has been widely used in screening DNA libraries in colony and phage plaque hybridization in recombinant DNA laboratories.[11] Traditional recombinant DNA applications include bacterial colony and phage plaque screening, plasmid DNA screening by agarose gel and/or Southern blot hybridization. Recent additions include in situ hybridization and fluorescence in situ hybridization (FISH), microarray or gene chip technology, DNA fingerprinting and its forensic applications. There are commercial kits based on DNA hybridization, including diagnostic kits for viral infection, cancers and inherited genetic mutations. More sophisticated diagnostic tools have entered the market in recent years, which involve amplification techniques such as PCR and bDNA. These usually require special equipment and/or expertise. DNA sequencing technology has now become a basic tool, not only for molecular biology, but also for many far-reaching projects such as the genome projects of human and other species. It is has also been used as a detection method in genotyping and pharmacogenetics.

3 PARAMETERS AFFECTING DETECTION SENSITIVITY

The methodology, the size and concentration of the target DNA and the levels of complexity and impurity of the test matrix can all affect the sensitivity of a detection system.

3.1 Definition of Sensitivity

A clear definition of sensitivity is essential for comparing one assay with another. A sensitivity unit should define both the lowest concentration of the target and the level of impurities in a test matrix in which the target is present. Often the target is a short stretch of DNA sequence and the test matrix is an aqueous solution of DNA of high complexity, such as genomic DNA. Thus, detecting one copy of the target DNA in 10^6 copies of genome of an organism is more sensitive than detecting one copy of the target DNA in 10^3 copies of the same genome because the former has a higher level of impurities than the latter.

3.2 Detection Method

The methodology often presets the upper limit of sensitivity of a detection system. The spectrophotometric method using OD at 260 nm detects only down to 250 ng mL^{-1} DNA. MS can detect subpicomolar levels of DNA, or a few hundred molecules in 0.1 μL, since this technique can use very little amount of sample. Although quick and direct if one has access to the equipment for these two techniques, neither of them can detect a sequence-specific target in a sample containing different DNA molecules. Agarose gel electrophoresis or PAGE can separate different DNA molecules by size,

and detect as little as 10 ng of DNA by ETBr staining. Combining agarose gel electrophoresis with Southern blot hybridization will increase the detection sensitivity to 10^6 molecules with very high specificity provided by the molecular hybridization with a sequence-specific probe.

To compare different methods more easily, we shall convert the mass of DNA into molar concentration. Assuming that the DNA target is a 300 bp fragment, it is interesting to find that 10 ng contains 3×10^{10} molecules. The size of DNA is in reciprocal relation to the number of molecules; for the same mass, the larger the DNA fragment, the smaller is the number of molecules.

The sensitivity and specificity of an indirect, amplification-based detection system is usually higher than that of a direct DNA detection method. The bDNA technique can detect as little as 50 molecules of a target-specific sequence in a sample containing different sequences. PCR can detect as little as one molecule of a target-specific sequence in 500 000 human cells or 10^6 copies of human haploid genome.[12] This sensitivity, if calculated for the mass ratio, is equivalent to detecting 1 in 7.2×10^{12} equivalent copies of DNA (the amplified PCR product is 417 bp. Since there are two genomes per diploid human cell and approximately 3×10^9 bp per genome, 500 000 human cells contain $2 \times 5 \times 10^5 \times 3 \times 10^9$ bp DNA. Therefore, 417 bp/$(2 \times 5 \times 10^5 \times 3 \times 10^9)$ bp $= 1/7.2 \times 10^{12}$, or 1 per 7.2×10^{12} equivalent copies of DNA). In this respect, PCR is the most sensitive and specific detection method in analytical chemistry.

3.3 Size of DNA

Depending on the method of the assay, the size of the target DNA may or may not affect the detection sensitivity. Spectrophotometry and agarose gel electrophoresis may detect 250 ng mL^{-1} and 10 ng per band, respectively, regardless of the size of DNA. Since the size of DNA is in a reciprocal relation to the number of molecules for the same amount of DNA, these methods have a higher sensitivity in detecting larger size DNA when the sensitivity is expressed as the smallest number of molecules detected. On the other hand, PCR is less sensitive in detecting large-size DNA because it is less efficient in amplifying larger DNA fragments. In detection systems based on the TaqMan® chemistry described below, it is desirable to choose a product size of 100–400 bp for optimum PCR amplification. However, it has been shown that PCR can detect one copy of a 1.4 kilobase (kb) DNA sequence in 10^6 copies of the human haploid genome, using the conventional gel electrophoresis and Southern blot hybridization method.[13]

3.4 Assay Optimization

It is relatively easy to optimize the detection conditions for direct detection methods. In spectrophotometry, an instrument that uses the least sample volume gives the highest sensitivity. Some current models of spectrophotometers can measure OD in a sample volume as small as 50 μL. Some models use a 96-well format quartz microtiter plate, offering both high throughput and sensitivity. A 50 μL volume of DNA at 250 ng mL^{-1} concentration contains only 12.5 ng of DNA. This sensitivity is equivalent to detection by agarose gel electrophoresis, although a more accurate OD measurement requires a DNA concentration of 1000 ng mL^{-1} or 50 ng of DNA in 50 μL.

PCR assay optimization involves both the amplification and postamplification steps. In assays that use agarose gel electrophoresis to detect PCR-amplified products, it is important to include the limitation of detection by gel electrophoresis. The smallest amount of DNA that can be detected in an ETBr-stained agarose gel is approximately 10 ng. As shown above, 10 ng of a 300-bp DNA fragment contains 3×10^{10} molecules. It requires a minimum of 37 cycles of PCR to amplify one molecule to 3×10^{10} molecules (assume 100% amplification efficiency. Let x be the number of PCR cycles required to increase the target sequence by 3×10^{10} fold, then we have $2^x = 3 \times 10^{10}$. Solve the equation to obtain $x \approx 35$. Since it takes two cycles to generate the first double-stranded PCR product bracketed by two PCR primers, it requires $n = 35 + 2 = 37$ cycles of PCR to amplify one molecule to 3×10^{10} molecules). This is very important information, because it tells us that unless we run 37 cycles of PCR we should not expect to see the target band in an agarose gel. Very often it is necessary to run more than 37 cycles to achieve one-copy sensitivity, because the amplification is rarely 100% efficient.

3.4.1 Real-time Polymerase Chain Reaction Detection of a Single DNA Molecule: One Example

The fluorescence detection of PCR product using the 7700 Sequence Detection System from PE Biosystems (Foster City, CA, USA) allows real-time detection and quantitation of DNA sequences without the need for labor-intensive processes such as gel electrophoresis and radioactive hybridization.[14,15] The 7700 instrument has a built-in 96-well format thermal cycler. The detection is based on the TaqMan® chemistry. The method uses a fluorescence oligonucleotide probe with a 5′ reporter dye and downstream 3′ quencher dye.[16] During PCR, the $5' \rightarrow 3'$ exonuclease activity of the *Taq* DNA polymerase releases the reporter, whose fluorescence can then be detected by the laser detector

of the 7700 instrument. Using this system, a 417-bp sequence of the *Herpes simplex* virus thymidine kinase gene (HSV-Tk) was amplified using primers 5′-CGAGACAATCGCGAACATCTAC-3′ (forward) and 5′-GCCAGCATAGCCAGGTCAAG-3′ (reverse) and a TaqMan® probe, 5′-FAM-CCGGCACAAACATC-GTGT-TAMRA-3′, that contains a covalently linked reporter dye FAM at the 5′-end and quencher dye TAMRA at the 3′-end. It has been shown that as little as one copy of the HSV-Tk gene can be detected in a background of 3.3 µg of genomic DNA, which is equivalent to 500 000 human cells.[12]

As shown in Figure 1(a–c), detection of one copy of DNA requires more than 45 cycles of PCR amplification using the PE 7700 system. To evaluate the results obtained with this real-time PCR, the amplified products were analyzed on agarose gels, followed by Southern blot hybridization. The presence or absence of hybridization for all of the reactions matched completely the results from the 7700. Differences between the intensities in

Figure 1 Amplification plots and hybridization results for (a) 0-, (b) 1- and (c) 10-copy of targets using the PE 7700 sequence detection system. Relative normalized fluorescence change (ΔR_n) is plotted vs time (PCR cycle number). (a) Four replicates of 3.3 µg of negative DNA (0 target); (b) six replicates of one target per 3.3 µg of DNA; (c) four replicates of 10 targets per 3.3 µg of DNA. The horizontal solid line spanning each plot depicts the threshold fluorescence intensity (0.013). Any sample that reached a fluorescence value that exceeded the threshold was considered to be positive, and the cycle at which this first occurred was defined as the threshold cycle (C_t). A sample for which no amplification occurred is given a C_t value of the total number of PCR cycles (60) performed. The isotopic Southern blot hybridization results of the amplified products at the end of the 60 cycles are shown in the insets, with the C_t values given. (Reproduced by permission of Eaton Publishing from Lockey et al.[12])

hybridization signals and the threshold cycle (C_t) values were probably caused by nonexponential amplification in the later cycles of PCR after the threshold. At a concentration of 10 copies per sample the C_t values of different samples were very close (43.3–43.9), but the intensities of hybridization signals varied significantly. This suggests that the use of C_t values for quantitation is more accurate than analyzing the product yields at the end of all PCR cycles. The former measures at the logarithmic phase of amplification. C_t values vary widely in the replicates of the one-copy samples. This suggests that quantitation is no longer accurate at such a low concentration. In other words, it is possible to detect one copy of DNA, but not possible to quantitate it by PCR. Unlike the detection of DNA in samples containing 10 copies of target molecules, detection of DNA in samples containing one copy of the target is not a 100% event. This will be discussed further later.

With proper assay development and validation, the PE 7700 automated amplification and detection system is able to achieve reproducibly one-copy sensitivity without the need for a time-consuming assay development process and highly experienced staff to analyze PCR products, making it an ideal system for clinicians and researchers who demand a high-throughput PCR assay. The method has been adapted to detect infection in patients treated with living pig tissues.[17] With the inclusion of a calibration curve based on known concentrations, it can be used for both high-sensitivity end-point detection and quantitation within one test.[17]

3.5 Levels of Noise or Impurities of the Test Matrix

The presence of impurities in a test sample may affect the specificity and sensitivity of the detection system. The OD method using spectrophotometry is greatly limited when impurities exist in similar amount to the target DNA, even if the impurities are not nucleic acids. The OD method is unable to detect the target sequence in the presence of other nucleic acids. For detection systems based on molecular hybridization, including PCR, it is possible to detect a target sequence in the presence of high levels of impurities and other nucleic acids.

During PCR, impurities of high concentrations of either nucleic acids or proteins may significantly reduce the detection sensitivity. It is possible to detect one copy of a target sequence in the presence of 6.6 μg of genomic DNA, which is equivalent to a DNA content of 10^6 mammalian cells in a reaction volume of 100 μL (Z. Long, unpublished data). When the reaction volume is reduced to 50 μL for the same PCR assay, the sensitivity is no longer one copy. The sensitivity can be restored to one copy when the nonspecific DNA level is reduced to 3.3 μg in a 50-μL reaction volume. Similar inhibitory effects on PCR have been observed in the presence of high concentrations of RNA, even when the target is DNA.

4 STATISTICAL ASSESSMENT OF LIMIT OF DETECTION: PROPERTIES OF SINGLE

4.1 Limit of Detection

The LOD is the lowest concentration of an analyte detectable in a sample by a well-defined assay with an acceptable detection confidence. Note that the level of analyte is not necessarily quantitated. Different assay systems may have very different LODs, and these have been described above. The LOD of a detection system is usually equal to the sensitivity of the system, except when the target copy numbers are low. For example, when the target copy number is one per sample and the detection sensitivity is one copy, the LOD may not equal one copy if only one replicate of the sample is tested because the detection confidence is only 63%. A confidence of less than 95% is usually unacceptable for statistical reasons. However, one can design a test strategy to analyze multiple replicates of a sample to achieve a one-copy LOD.

4.2 Theoretical Limit

Any detection method has a limit. It is important to understand whether the limit is caused by the instrumentation/methodology or by something more fundamental such as the probability laws. When an assay has demonstrated a sensitivity of one copy in an appropriate assay validation, the LOD has reached the theoretical limit. At the theoretical limit, detecting or not detecting the target is no longer a definite event, but an issue of probability or likelihood.

According to the Poisson probability distribution, if samples taken from a homogeneous solution have a concentration of one target molecule per sample volume, 36.79% of the samples will contain no target at all, and 63.21% will contain one or more targets (Table 1). Of the 63.21% positive samples, a good proportion of samples will contain two or more targets instead of one. As the target concentration increases, the chance of obtaining a positive sample also increases. To be almost certain that each sample will contain at least one target, the concentration has to be greater than nine targets per sample.

Theoretically, one can detect one target in a sample obtained from a solution that has a concentration of less than one target per sample because there is a chance that a sample may contain one target. However, one

Table 1 The Poisson probability distribution – average number of targets versus probability of a positive sample

Average number of targets	Probability of containing no target (%)	Probability of containing one or more targets (%)
1	36.79	63.21
2	13.53	86.47
3	4.98	95.02
4	1.83	98.17
5	0.67	99.33
6	0.25	99.75
7	0.09	99.91
8	0.03	99.97
9	0.01	99.99
10	<0.01	>99.99

cannot detect less than one target in a given sample. In a given sample, the number of targets follows a discrete distribution of whole number with a minimum of zero, but the concentrations of target in solutions are continuous. It is important to understand such a difference.

4.3 Properties of Single

The sensitivity of a detection system has reached its maximum when the assay has demonstrated its ability to detect one copy of DNA. To prove such a sensitivity, one needs to perform a series of tests using a number of replicate samples obtained from a homogeneous solution containing one copy of target DNA per sample volume. It may also be done with a two- or three-copy concentration. However, a higher copy concentration requires a larger number of replicate samples. The results from the tests can be analyzed by a Yates-corrected chi-square test, as described previously.[12] It is preferred that both the number of positive results and the number of negative results are ≥ 5 in performing the statistical test, in order to avoid misrepresentation of data. Theoretically, a higher target concentration corresponds to a smaller chance of obtaining a negative result. To reduce the sample size required to generate ≥ 5 negative and also ≥ 5 positive results, it is important to choose a concentration that has a similar probability of producing a balanced number of positive and negative results.

Although there is little that one can do to improve the sensitivity of a detection system once it has been optimized to detect one copy of DNA target in the appropriate test matrix, there is a lot one can do in designing the appropriate testing strategy to improve the probability of detection. The detection confidence of an assay is the probability of detecting a positive sample in one or more tests. At a concentration of one copy of target DNA per unit sample volume, the detection confidence can be increased to 95% by running three replicates of the test per sample. It can be further improved to a 98% detection confidence by using four replicates of the test (Figure 2a).

The relationships between the detection confidence and the number of replicates per test sample when the target concentrations are two and three copies per unit sample volume, are illustrated in Figure 2(b) and 2(c), respectively. For example, a 98% detection confidence can be obtained with only two replicates when the target concentration is two copies per unit sample volume. Up to 99.99% detection confidence is attainable with three replicates when the target concentration is three copies per unit sample volume. The probabilities of

(a)

(b)

(c)

Figure 2 Probability of detection as a function of target numbers and test replicates per sample. (a) One, (b) two and (c) three targets per sample.

different events with different combinations of positive and negative results are indicated in Figure 2(a–c). One can use these probabilities to design an appropriate testing strategy to optimize data collection and interpretation and minimize waste of resources. A conclusion that can be drawn from the analysis is that it must test multiple replicates of sample in order to achieve a statistically acceptable detection confidence of detecting one copy of the target or less in a sample. Conversely, as shown in Table 1, if one can only afford to run one replicate per test sample and want to have a 99.99% confidence of detection, one can choose to lower the claimed LOD of the assay to 9–10 copies. It is important to realize that this can only be done when the detection system has already demonstrated a one-copy sensitivity. It is the claimed LOD that is reduced, not the sensitivity.

4.4 Beyond the Limit

Is it possible to go below one copy of detection? Is there a limit to detection at all, knowing that everything is probable?

For low levels of target concentration (less than one copy per sample), according to the Poisson probability distribution [Equation 1]:

$$P = 1 - e^{-x} \tag{1}$$

where P is the probability of detection and x is the number of targets per sample (concentration). It is not difficult to find that there is a good chance of obtaining a positive sample even if the concentration is below one copy. For example, when $x = 0.1$, the probability of obtaining a positive sample is 9.5%. This is not a bad chance. However, to ensure a 99.0% detection confidence when $x = 0.1$, one must test at least 46 replicates of each sample (let the sample size be N, then $(e^{-0.1})^N = 1 - 0.99$; solve the equation to obtain $N \approx 46$).

Hence the answer to the second question is that the resources are the limit to achieving less than one-copy sensitivity. Because of the cost and availability of materials, it is not practical to go beyond one-copy detection sensitivity. As discussed in section 3.4, it is possible to detect low levels (one copy or less) of DNA, but it is not possible to perform quantitation at similar levels. Hence detection can go beyond the limit but quantitation can not.

5 THE PROS AND CONS OF DNA AMPLIFICATION

The major advantage of DNA amplification is its unsurpassed sensitivity. Better than finding a needle in a haystack, PCR has proved to be extremely sensitive and reliable, once optimized and validated. However, because of its great sensitivity, there is a misconception among beginners that the sensitivity is the cause of false-positive results. PCR has been known to have a high propensity to generate false-positive results. There are many publications on how to control the problem of PCR contamination.[18–25] Opposition to using PCR in critical areas such as diagnostic/forensic studies and quality control testing argues that PCR is inherited with contamination, so that applications of PCR are bound with faults. Some users even set 30 cycles as the maximum number of PCR cycles in order to avoid contamination. However, one should realize that it is neither the number of PCR cycles nor the sensitivity itself that causes false positives, but the laboratory environment, sample cross-contamination, contaminated equipment, reagents or poor techniques of the operator. It requires a minimum number of cycles (>30) and optimization to achieve one-copy sensitivity.[12,13] Such sensitivity can be obtained without contamination if proper procedures are implemented and strictly followed by the operator.

To control false-positive results, it is necessary to implement physical barriers, proper air pressure and separate air handlers between the areas for clean reagents and source DNA materials and between pre-PCR and postamplification processes. Clean protective clothing including face-masks, and hair and shoe covers is highly recommended. Setting up proper sentinel and PCR reagent controls is essential to demonstrate contamination-free reagents and laboratory environment. Because both amplification and detection processes are contained within a closed system in the PE 7700 instrument, it minimizes the potential for product carryover contamination. The use of uracil N-glycosylase (UNG) prior to PCR further reduces false positives by digesting previously amplified DNA products that contain uracil instead of thymine and are therefore subjected to UNG digestion.

Accurate results are critical for diagnostics, forensics and quality control testing of biological samples. This applies to any detection system. A false-negative result could result in transmitting an infectious virus to patients who used a failed product. A false-positive result could mean a suspension of clinical trials or a halt in manufacture of a product. All these are very costly to the sponsor. The principle of the statistical considerations and the PCR assay optimization strategy described here can save these troubles. A properly optimized and executed PCR test can provide very high sensitivity, comparable to and sometimes even better than the time-consuming infectivity culture assays. The distinct characteristics of single target detection are not limited to PCR and may

be applied to other detection systems that require single-copy sensitivity.

ABBREVIATIONS AND ACRONYMS

bDNA	Branched Deoxyribonucleic Acid
ETBr	Ethidium Bromide
FISH	Fluorescence In Situ Hybridization
HSV-Tk	*Herpes Simplex* Virus Thymidine Kinase Gene
LOD	Limit of Detection
MS	Mass Spectrometry
OD	Optical Absorbance
PAGE	Polyacrylamide Gel Electrophoresis

Hybridization of nucleic acid probes has been a key technique used in the exploration of the molecular biology of the cell. Use of this technique is now expanding into the field of clinical diagnostics for the detection of pathogens and genetic disorders. In a hybridization assay, a labeled nucleic acid probe of a particular sequence is used to detect the presence of a target nucleic acid sequence. The fundamental principals that guide the design of the nucleic acids hybridization probes and assays are reviewed in this article. New improvements that simplify the implementation of these assays and enhance their sensitivity are discussed. Coupling of hybridization with amplification of nucleic acids in vitro, which results in extremely sensitive detection of specific nucleic acids, are also described.

1 INTRODUCTION

Imagine that you have a magic reagent to which you add a droplet of a body fluid from a patient; you wait for a moment and a glow appears in the tube holding the mixture; the glow not only tells you which pathogen is responsible for the patient's illness, but also indicates which drugs to use to treat the disease. Also imagine that you can perform this diagnosis before any symptoms of the disease appear, improving the chances of success with the treatment, and you can perform this test on a large population with ease. The creation and development of such reagents are the promise of nucleic acid-based detection and are the aspiration of a diverse community of researchers. At the heart of nucleic acid-based detection is the process of hybridization, in which a strand of nucleic acid anneals to its complement. A nucleic acid probe can identify its complement in a sea of unrelated molecules. The bonds that form between complementary strands are among the strongest macromolecular associations known. This combination of high specificity and strong bonds gives the nucleic acid probes their advantage over conventional probes that are often based on antibody–antigen interactions.

When a macromolecular probe such as an antibody binds to its target, the forces that hold them together are electrostatic attractions, hydrogen bonds, salt bridges and hydrophobic interactions, and the bonds are located in a complex three-dimensional pattern. When one needs a protein with the ability to recognize a given target molecule, it is not possible to design it from its primary amino acid sequences, because the rules that predict the shape of a protein from its sequence are not well understood. Even after the rules of protein folding have become clear, this task will remain extremely complex. However, the diversity of the antibody repertoire within mammalian circulatory systems has allowed us to circumvent this hindrance by selecting antibodies that are specific for purified targets. On the other hand, the interaction between a nucleic acid probe and its complement is distinguished from the interaction between an antibody and an antigen by the number and organization of the contacts between the two molecules. A nucleic acid probe forms an ordered series of hydrogen bonds between the complementary nucleotides of the probe and the target strands, and the placement of the bonds is determined by the order of the nucleotides. The hydrogen bonds are placed in a fixed three-dimensional context by stacking interactions that occur between neighboring bases in each strand. These features permit the design of a nucleic acid probe for any given target nucleic acid by simply selecting a complementary sequence. Moreover, the strength and the specificity of the designed probes can be predicted with high precision.[1]

The technique of nucleic acids hybridization was first developed in the laboratory of Sol Speigelman.[2–4] A brief history of the key developments in hybridization technology has been described by Keller and Manak.[5]

The most familiar format for performing hybridization reactions has been to label the probes with radioactive atoms, fluorophores, or reporter enzymes, incubate them with denatured and immobilized DNA, remove the excess probes by extensive washing, and then detect the signal that is associated with the surface on which the target is immobilized. The amount of target can be quantitatively inferred from the strength of the signal. One of the most significant developments occurred after the discovery of restriction endonucleases and molecular cloning, which made it possible also to obtain information on the size of the DNA that contains the target of the probe.[6,7] In these assays, a DNA sample is incubated with restriction enzymes, the variously sized fragments that are generated are fractionated within a gel by electrophoresis and then blotted on a nitrocellulose membrane, and labeled probes are hybridized to the fragments on the membrane.[8] The analytical power of Southern blotting has made it a mainstay of molecular biology research. The power of this approach has been enhanced by the capability of generating single-stranded probes of defined sequence and high density labeling by in vitro transcription.[9]

The technique of hybridization has been utilized to explore the flow of information within cells and has been instrumental in the discovery of a number of biological phenomena. For example, the very first hybridization experiment[2] demonstrated that messenger RNAs are complementary to their DNA templates. The discovery that a large fraction of mammalian DNA contains small sequences that are repeated hundreds of times was accomplished in a very simple experiment in which the kinetics of reassociation of denatured calf thymus DNA were measured.[10] Intragenic noncoding sequences (introns) were discovered in eukaryotic genes by hybridizing mRNAs to genomic DNA and then observing in electron micrographs that regions of the genomic DNA looped out from the heteroduplex because they did not have complementary sequences in the RNA.[11] Hybridization reactions also have often been used to isolate homologous genes from other species. For example, from the knowledge that the *engrailed* gene in fruit flies is responsible for segmentation, it is possible to construct probes that can be used to isolate the homologous gene from humans, and to understand the role that it plays in human embryogenesis.[12]

Recent developments in hybridization technology allow it to be used for the detection of pathogens, mutations, and molecular rearrangements in clinical diagnostic settings and for forensic analysis. It is now possible to determine the extent to which a human tissue is infected with a pathogen by probing for the nucleic acids of that pathogen. This mode of pathogen detection is different from conventional immunoassays where the immune response of the body to the pathogen is detected. For this reason, it is possible to detect pathogens in absence of, or before the onset of, the immune response. Any pathogen can be detected from the knowledge of its nucleic acid sequence. Similarly, mutations that are related to disease state can be detected by simple and automated procedures.

2 HYBRIDIZATION FORMATS

The physical properties of nucleic acids that exhibit measurable changes upon hybridization are viscosity, absorption of ultraviolet light, and circular dichroism. The magnitudes of these changes are so small that millimolar concentrations of nucleic acid are required to observe the changes. Therefore, in order to measure the degree of hybridization for targets that are present in smaller concentration range in a sample, it is necessary to label the probes with a label that can be detected with higher sensitivity. These labeled probes are incubated with the sample, the hybrids are immobilized on a solid surface, and the excess of the probes is removed by washing the surface. Finally, the quantity of the label that remains after the washing is determined. Since these assays utilize both liquid and solid phases, their format is referred to as heterogeneous. Recently, it has become possible to detect hybridization in a liquid phase without having to immobilize and isolate the hybrids. These assays are called homogeneous assays.

3 HETEROGENEOUS HYBRIDIZATION ASSAYS

In order to isolate probe–target hybrids, a number of different solid surfaces and immobilization formats have been explored. Among the solid surfaces that are utilized are filter papers, nitrocellulose and nylon membranes, plastic beads, the walls of test tubes, and paramagnetic particles. Each surface offers unique advantages. Nitrocellulose binds to denatured DNA by adsorption, and slows down its renaturation, but at the same time permits hybridization with probes that are in excess. Nylon membranes are mechanically stronger than nitrocellulose membranes and do not become brittle when subjected to heating and drying steps, and they can therefore be probed multiple times. Magnetic beads are microscopic ferromagnetic particles that are coated with silanes and coupled with specific oligonucleotides or with other affinity agents such as streptavidin. Hybrids attached to the paramagnetic particles via the affinity agents and then can be isolated with a permanent magnet which causes the particles to stick to the wall

of the test tube and the supernatant can be withdrawn by aspiration.[13] Another advantage of paramagnetic particles is their large surface area, which provides a high binding capacity. Sometimes the surface of plastic dipsticks, test tubes or microtiter wells is used to immobilize hybrids.[14] Although this markedly simplifies the assays, this mode of hybrid immobilization suffers from poor binding capacity. Glass surfaces, such as microscope slides, are commonly used when the probes have a fluorescent label.[15]

There are a number of different immobilization formats for isolating probe–target hybrids from the excess of labeled probes. The most common method is to immobilize the denatured target nucleic acid and to perform the hybridization by immersing the solid medium in a solution of labeled probes. This is followed by washing the surface under conditions that maintain the hybrids but remove the excess probes. A second method is to immobilize a series of different probes at predetermined locations on a surface and then add labeled targets. In these assays, the location of the signal on the surface identifies the targets that are present in the sample. The third method is to perform the hybridization in solution and then immobilize the hybrids on surfaces. A fourth method is to perform assays in which the target is sandwiched between two probes, one of which serves as a label probe and the other serves as a capture probe. In these assays, the presence of the signal indirectly indicates the presence of the target, since the target bridges the signal and the capture probes. Finally, fixed tissue sections can be used for in situ hybridization, where the target molecules are naturally immobilized within the cellular matrix and the probes are hybridized to the targets at their original location.

3.1 Target Immobilization

Southern blotting is the most traditional and commonly used hybridization format, named after the developer of the technique.[8] This format is used in molecular cloning experiments to identify bacterial colonies that contain a particular nucleic acid target sequence. It is also used in the determination of the size of the RNA or DNA that contains a particular target sequence. The applications of this format range from the 'fingerprinting' of human DNA for forensics to the study of changes in the level of expression for particular RNAs upon treatment with drugs. In performing Southern hybridizations, the targets are denatured in situ, i.e. within the bacterial colony or within the gel that is used to segregate the nucleic acids by size, and then transferred to a nitrocellulose or nylon membrane. The DNA attached to the membrane is then hybridized to a radioactively labeled probe, excess probes are washed away, and autoradiography is performed to locate the position of colonies or bands.[16]

The power of this method is illustrated by an example in which different *Mycobacterium tuberculosis* isolates are typed in order to track the transmission of the disease in human populations. In this method, *Mycobacterium tuberculosis* is cultured from infected patients and its genomic DNA is isolated. The DNA is incubated with the restriction enzyme *Pvu II*, which cleaves it at a number of specific locations, generating a number of fragments of different lengths. Digested DNA from *Mycobacterium tuberculosis* bacteria that are isolated from different individuals are electrophoresed in different lanes of an agarose slab gel, in which different fragments are separated according to their size. The fractionated DNAs are transferred to a nylon membrane and hybridized to a 325-nucleotide long radioactively labeled probe that is specific for the insertion sequence *IS6110*. This insertion element, which is present at multiple sites, has a tendency to hop randomly from one place to another in the genome of *Mycobacterium tuberculosis*. Owing to this tendency of the insertion sequence, different sets of fragments are labeled by the probe for different strains of the bacterium. Thus, each strain produces a characteristic pattern of bands in the autoradiogram (Figure 1). Using this 'fingerprint', it is possible to identify each isolate and to chart the spread of a strain as it is transmitted within a population.[17]

Figure 1 Fingerprinting isolates of *Mycobacterium tuberculosis* by Southern hybridization. (Courtesy of P.J. Bifani and B.N. Kreiswirth.)

3.2 Probe Immobilization

The second most common mode of isolation of probe–target hybrids is via immobilized probes. In this format the probes are linked to unique positions on a solid surface and the target is labeled. This format permits the interrogation of a sample for the presence of multiple sequences, as a number of different probes can be linked to different locations on the solid surface. The location of the signals indicate which sequences are present in the sample. With the advances in the chemistry of DNA synthesis and immobilization, it has become possible to attach thousands of different probes in an area as small as 1 cm^2 and inquire whether a target contains their complement.[18,19] These high-density arrays of immobilized probes are commonly known as 'DNA chips'.

3.3 Hybrid Immobilization

Specific immobilization of probe–target hybrids is uncommon because of the lack of physical methods that can distinguish probe–target duplexes from unrelated double-stranded DNA. However, in the case of RNA–DNA hybrids, it has been possible to raise an antibody that recognizes RNA–DNA heteroduplexes. This antibody is used to immobilize the hybrids on solid surfaces. In these assays, the antibody that recognizes the RNA–DNA hybrid is attached to the surface of microtiter wells, the hybridization mixture is added to the well, and excess probes are washed away (Figure 2). The RNA probes are constructed in such a way that each probe carries many biotin moieties. A second antibody (or, in some cases, streptavidin) that binds to the biotin moieties in the probes and is also attached to a reporter is added to develop the signals.[20]

Figure 2 Detection of hybrids by immobilization of RNA–DNA heteroduplex.

3.4 Sandwich Hybridization

When hybridization is performed on solid surfaces with immobilized target or probes, the hybridization proceeds slowly and does not attain its full potential because the access to the targets or the probes is hindered.[21] In addition, the surfaces bind nonspecifically to labeled probes and thereby obscure the weak signals emanating from rare targets. One of the schemes that make the signals more dependent on the presence of the targets is sandwich hybridization, in which two probes are utilized simultaneously. The first probe serves as a capture probe, and can bind both to the solid surface and to the target. The second probe is a reporter probe, which can bind to the target at a second site and carries a reporter group. Thus, the association of the signal to the solid surface is strictly target dependent (Figure 3).

Usually, in sandwich hybridization assays the hybridizations are performed in solution and the hybrids are then transferred to a solid surface. Among the means for immobilization of the capture probes are biotin–streptavidin links or oligo-dT : oligo-dA links.[13,22] Sandwich hybridization reactions often decrease background signals to undetectable levels. However, when the detection is made highly sensitive, low-level background signals become significant. In order to reduce background signals further, a number of modifications in the basic sandwich hybridization format have been used. For example, in a reversible target capture scheme hybrids are eluted from paramagnetic particles after removal of the excess probes and recaptured on to the surface of a new set of paramagnetic particles. Nonspecifically bound probes which contribute to the background are discarded along with the first set of particles. The capture and release steps are repeated several times to attain extremely sensitive detection.[13]

Figure 3 Sandwich hybridization.

3.5 In Situ Hybridization

In situ hybridization is utilized to determine the location of specific nucleic acid sequences within tissues. It can also be used to detect specific sequences in particular subcellular domains, such as the cytoplasm, the nucleolus or the chromosomes. In situ hybridization reactions in entire organisms, such as insects or rodent embryos, are also possible. During in situ hybridization, the nucleic acid targets remain trapped within the cellular matrix, while remaining accessible to probes. In order to make the nucleic acids targets accessible to probes, while maintaining the cellular and histological integrity of the specimens, they are 'fixed' with reagents that remove membranes and cross-link proteins. Fixed specimens can withstand the rigors of hybridization, washing, and signal development.

The probes for in situ hybridization are radioactively labeled or labeled with tags that can generate color or fluorescence at the site of hybridization. In order to confine the signal to the hybridization site in intracellular localization experiments, ^{35}S-labeled probes and emulsion autoradiography are often utilized. The radiation from the ^{35}S radionuclide can travel only short distances and the photosensitive emulsion is in intimate contact with the specimen ensuring high-resolution images.[23] High-resolution images of the target distribution can also be obtained by utilizing fluorescence labels in thin tissue sections.

In the following example, in situ hybridization is used to map the distribution of two particular mRNAs within embryos of the fruit fly, *Drosophila melanogaster*. The target nucleic acids were *bicoid* and *oskar* mRNAs that localize at the anterior and the posterior ends of early preblastoderm embryos. RNA probes that are complementary to each of these mRNAs are prepared by in vitro transcription of the cloned genes encoding these RNAs. Digoxygenin-bearing nucleotides are incorporated into these probes during in vitro transcription. After permeabilization and fixing, the embryos are incubated with the probes. Excess probes are removed by several rounds of washing. The signal is developed in a series of reactions in which the embryos are first incubated with an antibody that is conjugated to alkaline phosphatase that can bind to the digoxygenin moiety. Further washing removes the antibody–alkaline phosphatase conjugates that are not bound to digoxygenin moieties and then a chromogenic substrate of the alkaline phosphatase, nitroblue tetrazolium, is added. A bluish-purple precipitate is created by the alkaline phosphatase wherever the RNA is localized. The gradient of color stemming from the two poles of the embryo indicated the distribution of the two RNA molecules (Figure 4).

Figure 4 Detection of localized mRNAs in an early embryo of *Drosophila melanogaster* by in situ hybridization. The *bicoid* mRNA localizes at the anterior end and the *oskar* mRNA localizes at the posterior end of the embryo. (Courtesy of P. Tolias.)

4 LABELS

A number of different labeling schemes, including the use of radioactive atoms, fluorescent moieties, chemoluminescence generating systems, and enzymatic reporters, have been explored in the construction of DNA probes, some of them having been inherited from immunoassays. Radioactive ^{32}P is a natural label for nucleic acids since it can be incorporated into their backbone during synthesis with radioactive nucleoside triphosphates. In order to improve the resolution of the autoradiograms, ^{35}S is used since the radiation from ^{35}S can only travel short distances. ^{35}S can also be introduced into the probes via radioactive nucleotide triphosphates. For reasons of safety, stability, and waste disposal, nonradioactive labels have been utilized. Among the nonradioactive labels that can provide sensitivity equivalent to radioactive labels are enzymatic labels that turn a colorless substrate into a colored product or turn a nonfluorescent substrate into a fluorescent product. Enzymatic labels can produce several thousand detectable products due to catalytic turnover. Commonly used enzymatic labels are alkaline phosphatase, horseradish peroxidase, and β-galactosidase.[24,25] Most often, enzymatic labels are introduced indirectly in the assay schemes because hybridization conditions denature proteins, and the bulk of the proteins may interfere with hybridization. A common mechanism of indirect labeling is to incorporate a small hapten such as a biotin moiety during the synthesis of the hybridization probe, add an enzyme-linked antibody for the hapten, and then remove the excess antibodies. Signals are developed by adding the substrate for the enzyme. In addition to chromogenic substrates, chemicals that can participate in a light-generating reaction are also commonly employed. These chemiluminescent labels provide very high sensitivity and can be used just like radioactive labels because both autoradiography and scintillation counting can be performed to

detect the signal.[24] Recently, fluorophores have become common labeling moieties. Fluorescent labeling moieties do not offer a sensitivity as high as radioactivity and enzymatic labels, but they have become popular because rare targets can be made to be more abundant by nucleic acid amplification. Another reason for using fluorescent labels is that high sensitivity can be achieved when localized signals are viewed under the microscope.

5 HOMOGENEOUS HYBRIDIZATION ASSAYS

Although hybridization assays that rely on the isolation of probe–target hybrids offer high sensitivity, they are cumbersome to perform. In addition, the requirement for immobilization and washing precludes their use in the real-time monitoring of processes that produce nucleic acids. It is necessary to sample the reactions at different times and quantify the products at a later time. In addition, in order to detect nucleic acids within cells, the cells have to be fixed to permit removal of the probes. It is desirable to follow the progress of nucleic acid synthesis reactions without interruption and to detect nucleic acids in living cells and organisms without killing them. Several assays have recently been developed that can detect nucleic acids in homogeneous solutions without the need to isolate the probe–target hybrids. These assays utilize interactive fluorescence reporters that exchange energy in a distance-dependent manner.[26]

The earliest homogeneous hybridization assays based on fluorescence resonance energy transfer (FRET) utilized two oligonucleotides that bind to neighboring sites on a target.[27,28] One probe in this binary probe system carries a donor fluorescent moiety at its 3′ end, and the other probe carries an acceptor fluorescent moiety at its 5′ end. The donor and acceptor fluorophores are chosen so that efficient energy transfer can take place from the donor to the acceptor when the two probes are in close proximity, whereas no energy transfer should occur when the two probes are apart from each other and are free in solution. Energy transfer, which is measured by the decrease in donor fluorescence or the increase in acceptor fluorescence, indicates the extent of hybridization and can be used to follow hybridization in real time (Figure 5a). An additional benefit of this approach is higher specificity, as two probes, rather than one, must bind to the target in order to generate a signal.

A second approach that uses FRET in homogeneous hybridization assays also uses a pair of oligonucleotides, one of which is designed to be complementary both to the target strand and to the other oligonucleotide. The 5′ end of one oligonucleotide is labeled with a donor fluorophore and the 3′ end of the other oligonucleotide is labeled with an acceptor fluorophore, such that when the two oligonucleotides anneal to each other the two labels are next to each other and exhibit efficient energy transfer. Since the binding of two small oligonucleotides is a dynamic process, when the target is added some of the oligonucleotides bind to the target, resulting in a decrease in energy transfer (Figure 5b). Thus, the extent of increase in the fluorescence of the donor fluorophore and the extent of decrease in the fluorescence of the acceptor fluorophore indicate the extent of hybridization.[29,30]

In a third approach, the donor and acceptor fluorophores are attached at two ends of the same

Figure 5 Different methods for detection of hybrids in a homogenous solution using interacting fluorophores. (a) Two probes bind to a target on adjacent sites and their fluorophores and interact via FRET. (b) Target binds to one of the oligonucleotides in a quenched pair of oligonucleotides and restores fluorescence. (c) The doubly labeled probe has a random coil conformation when it is free and a stretched-out conformation when it is bound to a target; FRET can take place in the free from, whereas it is precluded in the target-bound form. (d) On their own, molecular beacons are dark because their hairpin stem holds a quencher in close proximity to their fluorophore, whereas upon binding to a target they undergo a conformational reorganization that restores fluorescence.

oligonucleotide, which serves as the probe. Since an oligonucleotide in solution behaves like a random coil, the two ends sometimes come close enough to each other within the lifetime of the excited state of the donor fluorophore that some energy transfer occurs. However, when the probe binds to its target, the two ends are permanently kept away from each other, precluding energy transfer (Figure 5c). Although, the magnitude of the changes in energy transfer is relatively modest, it is possible to use it for monitoring hybridization.[31]

Another limitation of doubly labeled random-coil probes, in addition to the relatively small changes in fluorescence that occur upon hybridization, is that the magnitude of the changes decrease with the length of the probe. A fourth approach based on energy transfer solves these problems by introducing small complementary sequences on either end of the probe that brings the two labels in close proximity through the formation of a hairpin stem. The length of the stem sequences is chosen such that the formation of a probe–target hybrid readily disrupts the stem and removes the fluorophore from the vicinity of the quencher (Figure 5d). These probes, called molecular beacons, have an additional useful feature: the acceptor moiety is a nonfluorescent quencher dye.[32,33] As a consequence, nonhybridized molecular beacons are dark and hybridized ones are fluorescent (Figure 6). In addition, the hairpin stems of these probes bring the fluorophore and the quencher so close to each other that energy transfer takes place by more efficient mechanisms than FRET, resulting in a very high level of quenching. Furthermore, these close-distance energy transfer mechanisms do not require any particular relationship between the spectra of the fluorophore and the quencher, as FRET-based mechanisms do. As a consequence, well-quenched probes can be constructed from any fluorophore, allowing multiplex assays for many different targets in the same solution.

Figure 6 Detecting a specific nucleic acid in homogeneous solution with a molecular beacon. Two test tubes that contain a solution of the molecular beacon probe are illuminated with an ultraviolet lamp. The tube on the left also contains a target for the molecular beacon.

6 TARGET AMPLIFICATION

One of the reasons why hybridization-based assays did not find widespread utility in clinical laboratories for a long time is that targets that are clinically relevant are often rare constituents of biological samples. For example, pathogens, such as the human immunodeficiency virus, may be present in as few as one in 10^6 human cells, yet that individual may still be infectious. Another significant factor is the complexity of these assays. These limitations have been overcome by the development of techniques for the selective in vitro amplification of target nucleic acids. The most developed of these techniques is the polymerase chain reaction (PCR).[34] In this process, a specific nucleic acid sequence is amplified using two oligonucleotide primers, deoxyribonucleotides, a thermostable DNA polymerase, and a thermal cycler. The primers hybridize to opposite strands of the target sequence and initiate product strand synthesis by DNA polymerase and the thermal cycler denatures the double-stranded templates by raising the temperature. As the temperature of the reaction mixture is cycled between the stages of denaturation and annealing, the number of the DNA fragments defined by the two primers doubles every cycle. As a result of this exponential amplification, the target sequence is enriched more than 10^6-fold. After selective enrichment, the target sequences can readily be detected by hybridization.

In addition to the PCR, there are two other well-developed target amplification schemes: strand displacement amplification[35] and transcription-based amplification.[36] These techniques also utilize a pair of specific primers to amplify a region of the target. These methods accomplish the denaturation of double-stranded products by enzymatic means rather than via thermal denaturation, and the amplification can therefore be performed at one uniform temperature, eliminating the need for a thermal cycling device. Strand displacement amplification utilizes a DNA polymerase that displaces the DNA strand complementary to the template strand while extending the primer. The extendable 3′ ends are created by the nicking activity of a restriction endonuclease. The displaced strands serve as templates for further rounds of synthesis. As a result, the DNA is amplified exponentially as long as the primers and the enzymes remain in excess.[35]

Transcription-based amplification utilizes the RNA polymerase of bacteriophage T7, reverse transcriptase, and ribonuclease H in a concerted reaction. The initial RNA templates are copied by reverse transcription and one of the primers carries a tail corresponding to the bottom strand of the T7 RNA polymerase promoter. The original RNA in the resulting RNA–DNA hybrid is degraded by the action of ribonuclease H. The second primer then binds to the single-stranded DNA and is extended by the natural DNA polymerase activity of the reverse transcriptase, creating a functional promoter for the T7 RNA polymerase. The T7 RNA polymerase then generate more than 100 copies of the DNA template. Owing to the high turnover rate of T7 RNA polymerase, this reaction also produces large-scale amplification of the target.[36]

In order to result in amplification, both primers must bind to their targets in each cycle of PCR, and sometimes, especially with nucleic acids of high complexity, nonspecific products are also amplified. As a result, it is necessary to analyze the products of amplification by electrophoresis, followed by a hybridization step to identify the desired amplification product. In these confirmatory hybridization reactions, it is not necessary to use highly sensitive labels such as radioactive atoms or chromogenic enzymes. However, the assays remain labor intensive because of post-amplification analyses. In addition, the amplified DNA contaminates the laboratory and can become a source of false signals in future assays. Recently, the development of new homogeneous hybridization techniques has solved these problems by linking specific hybridization with nucleic acid amplification. It is now possible to perform extremely sensitive detection of specific sequences in a sealed assay tube.

The homogeneous hybridization techniques discussed above can be used to detect the product of amplification in the same tube in which the reaction is carried out. In addition, it is possible to monitor the progress of these reactions in real time, which enables quantitation of the initial template within an extremely wide dynamic range.[32,37,38] Although each of the target amplification schemes mentioned above can be monitored with a homogeneous hybridization method, we shall discuss the use of molecular beacons as an example of real-time monitoring of amplification reactions.

In order to monitor the progress of a PCR, a molecular beacon whose loop sequence is designed to be complementary to a region of the expected amplification product is included in the reaction mixture. The length of the arm sequences of molecular beacons is chosen so that the stem is stable at the annealing temperature of the PCR. The length of the loop sequence is chosen so that the probe–target hybrid would be stable at the annealing temperature also. During the denaturation step

Figure 7 Real-time measurement of amplicon synthesis during PCR using molecular beacons. (a) Change in fluorescence in seven reactions, each initiated with a different number of template molecules (indicated), is plotted against the number of cycles. (b) The threshold cycle, the cycle at which the signal becomes detectable, is plotted against the logarithm of the initial number of templates.

of the PCR, the molecular beacons assume a random coil configuration and fluoresce. As the temperature is lowered to allow annealing of the primers, stem hybrids form rapidly, preventing fluorescence. However, at the annealing temperature, the molecular beacons bind to the complementary strand in the amplified DNA and generate fluorescence. When the temperature is raised to allow primer extension, the molecular beacons dissociate from their targets and do not interfere with polymerization. A new round of hybridization takes place in the annealing step of every cycle, and the intensity of the resulting fluorescence indicates the amount of accumulated amplified DNA (Figure 7a). The number of thermal cycles that it takes for the fluorescence intensity to reach a detectable value is inversely proportional to the

logarithm of the number of template molecules that are initially present in a reaction (Figure 7b). These extremely sensitive and quantitative assays can be performed in a single tube and require one operational step in which the reaction mixture is assembled.

In addition to molecular beacon probes, other homogeneous methods of hybridization can also be used to monitor the progress of amplification reactions. FRET-based binary probes can be used to perform real-time PCR.[27] The two probes that bind to adjacent sites on the DNA strand being amplified are added in the initial reaction mixture along with the primers. In order to monitor the progress of the reaction in real time, the extent of resonance energy transfer is measured continuously during the reaction.[39] Similarly, random-coil probes labeled with two interacting fluorophores can also be used to monitor the progress of PCRs in real time. These probes can draw additional benefit from the natural 5′–3′ endonucleolytic activity of DNA polymerase, since this activity results in cleavage of the probe that the polymerase finds sitting in its tract during polymerization.[40,41] Since the cleaved fragments diffuse away from each other are not able to participate in FRET, the fluorescence increases and provides a measure of the progress of the PCR.[37] With reference to the 5′–3′ endonucleolytic activity of the Taq DNA polymerase, these probes are called TaqMan probes. Interfacing these homogeneous hybridization methods with amplification reactions allows the simple and sensitive detection of rare nucleic acids that are present in complex nucleic acid mixtures.

7 PROBE AMPLIFICATION

In vitro amplification of target sequences is highly effective for the detection of rare sequences. An alternative strategy is to amplify the signals associated with the probes themselves. For example, by using reporter enzymes it is possible to generate 1000 detectable signal moieties for every probe that is bound to its target. However, higher levels of amplifications are required for the detection of rare pathogens in clinical samples. There are three strategies that provide the required degree of amplification: RNA hybridization probes that can be amplified by Qβ-replicase, branched-DNA probes that form dendrimeric complexes, and padlock probes that can initiate rolling circle amplification. Assays based on these signal amplification techniques are as sensitive as those based on target amplification techniques.

The Qβ replicase-mediated amplification system relies upon bifunctional recombinant RNA probes that can serve as hybridization probes and can be amplified exponentially upon incubation with the RNA-directed RNA polymerase isolated from *Escherichia coli* infected with bacteriophage Qβ.[42,43] This system exploits the ability of Qβ replicase to amplify naturally occurring RNA templates such as midivariant-1 (MDV-1) RNA. These RNAs have evolved to serve as templates for Qβ replicase. Their replication does not require primers and strand separation occurs naturally at 37 °C owing to the self-structure of the RNA and to the action of the replicase. RNAs that replicate exponentially possess an internal replicase binding site, a particular 3′-terminal sequence for the initiation of replication, and a particular 5′-terminal sequence that encodes the 3′-terminal initiation sequence needed for the initiation of synthesis from the product strand. Hybridization probe sequences are inserted within a region of the MDV-1 RNA that preserves the elements that are necessary for replication.[44] In order to perform assays that detect rare targets, these probes are hybridized to the target along with capture probes, the hybrids are collected on the surface of paramagnetic particles, excess of the probes is removed by washing, the hybrids are eluted into a solution, and finally Qβ replicase is added to the eluted hybrids, amplifying the probes 10^{11}-fold in a 30-min incubation.[45] The amplified RNA can be detected by fluorescence of an intercalating dye. In order to ensure that the nonspecifically bound probes that survived the stringent washing do not produce a signal, an additional target-dependent step has been interjected in these assays. This involves using recombinant RNA probes that are broken into two pieces in the middle of the probe region, neither of which can be amplified exponentially on its own. However, when the two segments of the probe are brought next to each other by binding to the target, they can be ligated together, generating fully functional replicating RNA (Figure 8). With binary hybridization probes that become replicatable by the mediation of the target, it is possible to detect as few as 100 copies of a target in a complex nucleic sample.[46]

A second approach which relies on the hybridization probes to give a signal that is substantially larger than the number of probes is based on the use of branched DNA probes. These probes bind specifically to their target and carry multiple branches that stem from the hydroxyl functionalities of the deoxyribose sugars. These branches themselves are oligonucleotide sequences to which other branched DNA oligonucleotides can be attached. Depending upon the valency of each branched oligonucleotide and upon the number of successive layers that are used, a very large dendrimeric structure can be assembled. Reporter enzymes are attached at multiple locations on the branches of these dendrimers. Thus, each target sequence results in a large number of detectable labels after the signals are developed.[47]

Figure 8 Detection of a rare target RNA by probe amplification with Qβ-replicase. The details of the physical and enzymatic steps are described in the text. (Reproduced by permission from Tyagi et al.[46] Copyright 1996 National Academy of Sciences, USA.)

In a third approach, circularizing oligonucleotide probes (padlock probes) are utilized. The 5′ and 3′ end regions of these linear oligonucleotides are designed to base pair next to each other on a target strand. If properly hybridized, the two ends can be joined by target-dependent enzymatic ligation, converting the linear probes to circular molecules that are catenated to the target sequence.[48] Owing to this topological linkage with the target, the hybrids can be washed with extremely high stringency, markedly enhancing the assay specificity. The probe remains associated with the target molecule even when the hybrid is disrupted. This permits localized detection of target sequences on a chromosome with fluorescence. In addition to permitting stringent washing, the circularized probes allow signal amplification by a rolling-circle replication mechanism. In this DNA synthesis process, a primer is annealed to the circle and extended with a DNA polymerase. DNA polymerase extends the primer using the circle as a template and when it reaches the tail of the primer the polymerase begins to displace the primer and the extended product. Product strand displacement continues indefinitely, resulting in the synthesis of a very long DNA containing a tendemly repeated copy of the circularized probe.[49] This multimeric linear copy of the probe can be exponentially copied by including a second primer that can bind to the product strand. When the second primer binds, a cascade of DNA synthesis and strand displacement ensues, resulting in the synthesis of a large amount of DNA. This serves as a signal indicating the presence of the target to which the circularizing probes were initially bound.[50,51]

8 MUTATION DETECTION

Accelerated by the human genome project, a large number of genetic variations are being discovered, some of which are linked to genetic disorders. Therefore, the task of detecting specific sequences often involves distinguishing closely related sequences that can differ from each other by only a single nucleotide substitution. Although oligonucleotide probes are exquisitely specific, their power to discriminate between closely related targets decreases as their length increases. As the length of the probe is increased, the free energy penalty resulting from a mismatched base pair in a probe–target duplex represents a smaller and smaller fraction of the total free energy change associated with binding. Consequently, allele-specific oligonucleotides for a target region have to be found by making them progressively smaller and by making the conditions of hybridization progressively more stringent. Several groups have described ways of improving the specificity of oligonucleotide probes by making them more structured.[52] This can be accomplished by embedding the oligonucleotides within hairpin stems or by circularizing them.[33,53] Alternatively, specific enzymes that recognize matched or mismatched base pairs are recruited to enhance the level of discrimination.[54,55]

In order to detect single-nucleotide variations in clinical diagnostic settings, or for the discovery of relationships between genotype and disease, it is important to be able to perform accurate assays on a large number of samples.

A number of techniques that have been conventionally used for the detection of mutations have been described by Cotton.[56] There are two recent techniques that can accurately detect mutations and can be used in formats that have high throughput: one is based on the use of homogeneous hybridization probes coupled to PCR, and the second is a cleavage assay that utilizes the specificity of 'flap' endonuclease from *Pyrococcus furiosus*. The first technique employs real-time PCRs to amplify a region of the DNA that contains the single-nucleotide variation of the interest in the presence of a pair of homogeneous hybridization probes. Either molecular beacons or Taq-Man probes can be employed in these assays. One of the probes is specific for one allele and is labeled with one color, whereas the second probe is specific to the other allele and is labeled with a different color. The color that develops indicates which allele is present.[57–59] Since 96 reactions can be performed in parallel and the analysis is performed as the PCR proceeds, the throughput of these assays is so high that the genotypes of thousands of samples can be determined every week.

The cleavage assays utilize a flap endonuclease from *Pyrococcus furiosus* to cleave Y-shaped structures that are created by hybridizing two oligonucleotides to the region of the target at the site of the mutation (Figure 9). These Y-shaped structures are akin to those that arise naturally during DNA synthesis when the 3′ end of a growing chain displaces the sequence that is bound to the template. The sequence in the displaced strand and the newly synthesized strand are the same and undergo back-and-forth branch migration. A number of enzymes

Figure 9 Schematic representation of the branch migration and cleavage in the mutation detection assay using flap endonucleases. The invader probe has the same sequence at its 3′ end as the signal probe has at its 5′ end. Flap endonuclease can cleave the signal probe only when the nucleotide at the 3′ end of the invader probe is perfectly paired.

associated with DNA repair, including DNA polymerase and flap endonuclease from *Pyrococcus furiosus*, have the capacity to excise these redundant portions of displaced DNA by nicking the displaced strand where it meets the template strand. The artificial Y structures are created by binding an 'invader oligonucleotide' and a 'signal oligonucleotide' to the target at the same time (Figure 9). The 3′ end of the invader oligonucleotide share the same sequence with the 5′ end of the signal oligonucleotide, permitting branch migration to create a substrate of the flap endonuclease. Cleavage results in a detectable signal, as FRET between the terminal labels of the signal probes is disrupted. Y-structures possessing a mismatched base pair at the junction of the two arms can not be cleaved. Hence, by using two variants of the signal probe where each is specific for a different allele and has a different reporter fluorophore, it is possible to discriminate between two alleles. The system is highly specific, because the specificity of the flap endonuclease is added to the specificity of hybridization probes.[55]

9 TAKING DNA PROBES INTO A PROTEIN WORLD

All of the hybridization assays described so far make use of the ability of nucleic acid strands to anneal specifically to their complements. A new kind of DNA probe is being developed that expands the utility of nucleic acids beyond their traditional role as hybridization probes. These oligonucleotide probes do not hybridize to a complementary nucleic acid, but rather they bind to a protein target.[60] These oligonucleotide probes assume a conformation that allows them to fit within a pocket of their protein target. These oligonucleotides are created and used in the image of antibodies. From the vast field of possible shapes and structures inherent in a partially or fully randomized collection of oligonucleotides, it is possible to isolate an oligonucleotide that can bind to any target of interest. A library of all possible sequences is created on a DNA synthesizer and an in vitro selection scheme is used for the isolation of a desired molecule. Methods of in vitro evolution and selection which allow for the isolation of a particular sequence from hundreds of billions of other possibilities were first introduced in 1967.[61] These methods have recently been invigorated by the use of PCRs. Using a scheme termed SELEX (systematic evolution of ligands by exponential enrichment),[62] it has been possible to find nucleic acid ligands for a wide variety of molecules including proteins and organic dyes.[63] In this scheme, a library of oligonucleotides is panned for the molecules that exhibit an affinity for a desired target. Those that are capable of binding to the target are

exponentially amplified. This process is repeated until a molecule of desired specificity and affinity is found. For example, SELEX has been used to find a DNA ligand for vascular endothelial growth factor, a protein involved in angiogenesis. Using this DNA ligand as a detector probe and an antibody as a capture probe, an assay has been developed for the detection of vascular endothelial growth factor.[64] The DNA ligand was tagged with a fluorescein moiety in order to produce a chemiluminescent signal via an antifluorescein antibody and an alkaline phosphatase detection system. This assay exhibits a specificity equivalent to common immunoassays.

The advantage of using nucleic acid ligands for proteins, as opposed to antibodies, is that animals are not required for the development of the diagnostic reagent. It may be possible to find ligands for poorly immunogenic targets. Knowledge of the sequence of a nucleic acid ligand allows its accurate reproduction anywhere in the world since its production is not subjected to animal-to-animal variations. For applications and detection methods in which the bulk of the antibodies is a limitation, the small size of nucleic acid ligands offers an advantage. In the conventional nucleic acid-based diagnostics, one can easily identify probes that characterize a pathogenic species or strain by using the knowledge of the nucleotide sequence of relatively invariant regions of genomes. Similarly, finding the antibodies for conventional immunoassays is also simple, because all one needs is an antigen, a syringe, and an animal. Based on the diversity of ligands isolated by SELEX, developers of this technique predict that nucleic acid ligands will also prove to be as general and easy to find as conventional nucleic acid probes and antibodies.

10 FUTURE PROSPECTS

The technique of hybridization has played a key role in the exploration of the molecular biology of the cell. Improvements that simplify its implementation and enhance its sensitivity are taking it to the realm of clinical diagnostics, where it is important that the technique is simple to perform and is amenable for automation. These developments will make it possible to map the distribution of mRNAs in living cells by microscopy and study gene expression in an ensemble of living cells with fluorescence-activated cell sorters.[32] We shall see innovative use of DNA–DNA hybridization in the development of new materials for the construction of nanostructures.[65] In addition, we shall witness the solution of computational problems by the utilization of the manifest specificity of oligonucleotides.[66]

DNA molecules with unusual structures can have significant consequences in many DNA metabolic processes. This article summarizes structural studies of DNA molecules containing bulged and mismatched bases and trinucleotide repeating DNAs. Extra base bulges and mismatches in double-stranded DNA can arise from replication errors or imperfect recombination. If these lesions escape the repair system, they would subsequently cause mutagenesis. Using a combination of gel electrophoresis, electron microscopy (EM), chemical modification, and probing with RecA protein, the structure of bulged and mismatched DNAs was examined and factors such as base composition and flanking base sequence have been shown to influence the overall structure of these molecules.

Expansion of trinucleotide repeats is a major cause of several inherited neurodegenerative diseases. Described here are findings that show, by in vitro nucleosome assembly assay, that the expanded CTG triplet sequences derived from myotonic dystrophy (DM) patients form the most stable naturally occurring nucleosomes that are known. In contrast, long tracts of repeating CCG triplets (expanded in fragile X syndrome (FraX) patients) resist nucleosome assembly. This information could provide critical clues about how these unusual DNAs cause harmful biological effects in living cells.

1 INTRODUCTION

DNA molecules can possess structural polymorphism depending on base composition, sequence arrangement, and many other factors. Various structures of DNA molecules could determine their fate in DNA metabolic processes. Our research interest is to understand the structure and function of unusual DNA sequences which could cause mutagenesis and diseases in living cells.

Extra base bulges and mismatches in double-stranded DNA can arise from recombination between sequences that are not fully homologous or from errors of replication. Bulged bases resulting from replicative errors are considered to play an important role in frame-shift mutagenesis.[1] In *Escherichia coli*, mismatches can be repaired by the methyl-directed repair system and several short-patch mismatch repair pathways, and the repair efficiency depends on the type of mismatch and the sequence context.[2] Genetic studies have shown that single-base bulges can also be repaired by the methyl-directed repair system in *E. coli*[3] and, using cell extracts, this repair system has been shown to repair DNAs containing 1–3-base bulges as efficiently as a G·T mismatch.[4]

Human homologs of mismatch repair proteins have been identified: hMSH2-6 are bacterial MutS homologs and hMLH1, hPMS1, and hPMS2 are homologs of bacterial MutL.[5] Mutations of these genes have been shown to be responsible for almost all patients with hereditary nonpolyposis colorectal cancer, in which simple repetitive DNA sequences have a high incidence of mutation.[6] Biochemical and genetic studies have demonstrated that these human repair proteins possess different affinities for DNA containing bulges and mismatches depending upon the type and number of bases. Therefore, it is critical to understand the structure of DNA containing bulges and mismatches and examine the determining factors such as base composition, flanking

sequences and number of bases. This article describes our studies using a variety of biochemical assays to investigate the structure and properties of short duplex DNA molecules containing bulged and mismatched bases.

Since 1991, 12 human genetic diseases including DM and FraX have been shown to be caused by expansion of trinucleotide repeats.[7–10] In each disease, an expanded block of repeating trinucleotides is present in or near a gene whose loss or alteration leads to the disease. The repeating triplet blocks present in normal individuals at these loci are heterogeneous in size and have less than 35 copies. In the afflicted person there can be as many as 2000 repeats. The diseases have been divided into two groups based on the location of the expanded triplet within the disease gene. The first group includes DM, FraX and Friedreich's ataxia, in which the triplet blocks are not in the protein coding regions. In these diseases, the triplet blocks must expand beyond ~100 repeats for the full disease symptoms to appear and perfect triplet runs are much more deleterious than longer blocks that contain scattered interruptions.[10–15] In the second group, including Huntington's and Kennedy's diseases, the expanded triplet repeats are within the protein coding sequences. Thus, expansion by a smaller number of CAG/CTG repeats that encode polyglutamine tracts in the disease protein alter or abolish its activity. The triplet diseases frequently show unusual genetics (anticipation), in which the severity of the disease increases with succeeding generations. Disease symptoms also correlate with the size of the expanded triplet block.

For each triplet disease, two major questions need to be answered: what is the mechanism of expansion of triplet repeats?; and how does the expanded triplet repeat in each disease lead to clinical symptoms? In this article, we summarize our studies, showing that repeating sequences CTG (in DM) and CCG (in FraX) have extremely unusual properties in forming nucleosomes. Thus, the biological manifestations of DM and FraX diseases are likely to be due in part to the unusual properties of DNAs containing very long triplet repeats and the resulting unusual chromatin structures.

2 STRUCTURE AND PROPERTIES OF DNA CONTAINING BULGES AND MISMATCHES

Structural studies using nuclear magnetic resonance (NMR) spectroscopy suggest that bulged bases can exist in either a stacked-in or looped-out conformation depending on the base composition of the bulge, temperature, and other factors.[16–21] Gel electrophoretic studies in our laboratory (see below) and the laboratories of Lilley and Crothers have shown that bulges of 1–5-bases produce kinks in DNA, which result in decreased mobilities of bulged DNAs in polyacrylamide gels.[22–25] Whereas single-base bulges produce kinks in DNA, studies using NMR,[26] X-ray crystallography[27] and gel electrophoresis[22,23,28] show that single-base mismatches do not. Furthermore, DNA containing multiple base mismatches shows no retardation of gel mobility in 15% polyacrylamide gels.[22] These results suggest that mismatched bases remain stacked into the helix and produce at most only subtle perturbations in the DNA helix.[28]

We have applied a combination of gel electrophoresis, EM, chemical modification, and RecA probing techniques to understand further the structure and properties of short duplex DNA molecules containing either bulges or mismatches.

2.1 Gel Electrophoretic Analysis of DNAs Containing Base Bulges and Mismatches

Gel electrophoresis and EM have been used to examine the effects of 1–4 extra bases on the structure of DNA. DNA duplexes of 32 basepairs (bps) were synthesized containing unique single-stranded ends such that upon ligation the 32-mers can only join in a head-to-tail fashion. The 32-mers were synthesized to contain various arrangements of single or multiple extra bases. The effect of the extra bases on each 32-mer was amplified by the ligation process which places the extra bases in phase with the helix in the linear and circular multimers. It was observed that single extra bases caused a marked retardation of the electrophoretic mobility of the linear multimers, indicating that the bulged bases kinked the DNA. Analysis of the size distribution of the circular multimers confirmed this observation. DNAs with two to four extra bases at a single site showed even greater electrophoretic retardations and yielded smaller circular multimers. Placing the extra base(s) out of phase with the helix created kinks which canceled each other and produced no net retardation.[23]

The effects of bulge composition and flanking sequence on the kinking of DNA by bulged bases were further investigated in this way. Synthetic 30 bp duplex DNAs containing two single-base bulges spaced by 10 bp were ligated head-to-tail, and their electrophoretic behavior in highly cross-linked gels was examined. All bulge-containing DNAs showed marked electrophoretic retardations compared with non-bulge-containing DNA. Regardless of the sequence of the flanking bps, purine bulges produced greater retardations than pyrimidine bulges. Furthermore, bulged C and Ts produced the same retardations as did bulged G and As. Bulged DNA containing different flanking bps showed marked differences

Figure 1 Effect of different bulged bases on the electrophoretic mobility of DNA. DNA duplexes were ligated head-to-tail, electrophoresed through a 15% polyacrylamide gel, and visualized by staining with ethidium bromide. The apparent size of the DNA in each band of a gel was determined relative to the mobility of *Hae*III-digested φX 174 DNA fragments. The κ value is defined as the ratio of the apparent size of a DNA fragment to its actual size. These κ values were plotted against the actual size of the DNA as multiples of the monomer length.

in electrophoretic mobility, for example, the G·C and C·G flanking bps were seen to have very different effects (Figure 1). Thus, these results imply an important role of base stacking in determining how neighboring bps influence the kinking of DNA by a single-base bulge.[28]

We have applied the same techniques to examine DNAs containing single-base mismatches. Twenty-four DNAs containing eight possible mismatches with three different flanking sequences (A·T, G·C, or a combination of the two) were analyzed on 15% polyacrylamide gels and showed no detectable retardation in electrophoretic mobility.[23]

2.2 Visualization of Three-base Bulged DNAs by Electron Microscopy and Estimation of the Kinking Angle Produced by the Bulges

The demonstration that bulged bases produce electrophoretic retardations has provided a means of screening for small chromosomal deletions or insertions. For example, nearly 70% of the carriers of cystic fibrosis (CF) in the western Caucasian population possess a single three-base deletion (ΔF_{508}) in the CF gene on chromosome 7.[29] Several groups have used the polymerase chain reaction (PCR) to amplify small regions of DNA (100 bp) around codon 508 of the CF gene;[30–32] if the DNA is from a carrier of the disease and thus a heterozygote, amplification produces four single-stranded DNA fragments, two that contain the deletion and two that do not. Upon annealing the four DNA strands, two homoduplexes and two heteroduplexes (one containing a CTT bulge and the other containing an AAG bulge) are produced, and the latter species can be detected by their retarded electrophoretic mobility. This approach has also been used to screen for a four-base insertion mutation in Tay–Sachs disease.[33,34]

For these genetic screens to be useful and to understand further the structure of bulge-containing DNA, it is important to measure directly the kinking angle produced in a DNA by a bulged base and to examine the distribution of kinking angles within the population of bulged DNAs. To approach this problem we obtained DNA from a CF carrier. The CF homoduplex and bulge-containing heteroduplex molecules were prepared as described above. These DNAs were examined by EM for the presence of visible kinks. Twice as many bulge-containing

Table 1 EM analysis of PCR-amplified CF DNA (2584 molecules scored)[a]

DNA	Molecules straight (%)	Molecules with a bend at the center (%)
PCR-amplified:		
Heteroduplexes	58	42 (14)
Homoduplexes	76	24 (3)
75 bp DNA	83	17 (2)
Synthetic:		
CTT-bulged DNA	62	38 (13)
AAG-bulged DNA	61	39 (12)
85 bp DNA	81	19 (3)
82 bp DNA	81	19 (3)

[a] DNAs amplified by PCR[35] from the DNA of a CF carrier were annealed to produce homoduplexes and heteroduplexes and fractionated on polyacrylamide gels. A 75 bp DNA with no bulged bases served as a control. In a separate experiment, four DNAs were prepared from synthetic oligonucleotides: a DNA with an AAG bulge in the one strand, a DNA with a CTT bulge in the other strand, an 85 bp DNA with no deletion in either strand, and an 82 bp DNA with the three-base deletion in both strands. The DNAs were prepared for EM as described elsewhere.[36] In fields of molecules, the number that were straight or bent by less than 30° were scored against those which appeared to have a central kink of 30° or greater, as judged by eye. Number in parentheses indicates the percentage of the total molecules that contain a kink 40–60% from one end of the DNA and in which the kink measures between 70 and 90°. A kink of 0° represents a perfectly straight molecule.

DNAs were seen to have a central kink as compared with the non-bulged controls (Table 1). Examination of the distribution of kinking angles showed that the bulged population contained 5–7-fold more molecules with a central kink of $80 \pm 10^{\circ}$ than did the control molecules (Figure 2a–c and Table 1).

Examination of the DNAs synthesized to contain just the CTT or AAG bulges and the respective homoduplexes revealed a similar distribution of kinked and straight molecules as seen in the PCR-amplified DNA (Table 1), and the angular distribution of kinks (data not shown) was nearly identical for both.

2.3 Binding of RecA Protein to DNAs Containing Base Bulges and Mismatches

Previous studies have shown that thymine dimers,[37] (6–4) photoproducts,[38] psoralen cross-links,[39] and intercalating drugs[40,41] can promote the nucleation of RecA protein binding on double-stranded DNAs in the presence of adenosine-5′-*O*-(3-thiotriphosphate) (ATPγS), a poorly hydrolyzed analog of ATP. Other structural variations such as B–Z junctions,[42,43] changes in DNA superhelicity,[44] and an A·T-rich sequence[45] also enhance the binding of RecA protein to double-stranded DNAs. These observations suggest that RecA protein recognizes perturbations in the DNA helix. To test the hypothesis that RecA protein is intimately involved in repair,[46,47] it would be of value to examine the interaction of RecA protein with two lesions that are frequent products of DNA metabolism: bulged bases and single-base mismatches.

Using a nitrocellulose filter binding assay, we examined DNA duplexes containing 1–4-base cytosine bulges and the control DNA. Upon incubation with RecA protein in the presence of ATPγS, DNA with a one-base cytosine bulge showed similar kinetics of RecA binding as compared with DNA lacking a bulge (Figure 3). RecA bound to DNA containing two- or three-base cytosine bulges with a similar kinetics and both showed higher levels of binding compared with the control DNA. DNA containing a four-base cytosine bulge showed even higher binding (~30% more than the control). These results suggest that RecA protein recognizes the perturbation produced by the bulged bases.

Gel electrophoretic studies have demonstrated that single purine bulges in DNA cause greater retardation than single pyrimidine bulges (see above). This suggests that purine bulges introduce kinks of a greater angle into the DNA helix as compared with pyrimidine bulges. To determine whether any correlation exists between the kinking angle and RecA binding, a set of DNAs containing 1–4-base adenine bulges was investigated. Interestly, we found that RecA bound to DNA containing

Figure 2 Angular distribution of kinking angles. The CF DNAs from PCR amplification, a pool of both heteroduplexes (a), both homoduplexes (b), and the 75 bp control DNA (c) were prepared for EM. From the micrographs, the kinking angle in each kinked DNA was measured, in addition to its position relative to the DNA ends. For those molecules in which the kink was within 10% of the center, the angle of the kink was plotted. Approximately 100 bent molecules for each sample were measured. A cut-off of angles less than 30° was imposed by eye.

Figure 3 Binding of RecA to DNAs containing 1–4-base cytosine or adenine bulges. Duplex DNAs containing central 1–4-base cytosine bulges (C1, C2, C3, or C4), 1–4-base adenine bulges (A1, A2, A3, or A4), and the control DNA (control) were prepared by annealing the ^{32}P-labeled upper strand (the strand containing extra bases) with the complementary lower strand. The labeled DNA (4 μg mL^{-1}) was incubated with RecA protein at a concentration of 240 μg mL^{-1} in the presence of ATPγS at a final concentration of 200 μM. The efficiency of RecA binding was determined by the filter binding assay.

a four-base cytosine bulge much more efficiently than to DNA with a four-base adenine bulge, although four-base adenine bulges produce kinks of a greater angle than four-base cytosine bulges (Figure 3). Further, RecA bound to two- and three-base adenine bulged DNA with higher affinity than to the four-base adenine bulged DNA. The results suggest that the degree of kinking is not the only determinant of RecA binding. Comparison of the chemical sensitivity of two DNAs, one containing a four-base adenine bulge and the other a four-base cytosine bulge while bound by RecA protein revealed a similar chemical accessibility at the 5′ side of the bulges, but higher accessibility at the 3′ side of the bulge for the cytosine bulged DNA. We concluded that the degree of binding of RecA protein to bulged DNA was dependent on the conformation of the bulged bases and the kinking angles produced by the bulges as determined by the type and number of bases in the bulge (Figure 3).

Although a single-base mismatch does not kink DNA (see above), RecA protein showed preferential binding to DNAs containing certain single-base mismatches (Figure 4a and b). Moreover, DNAs containing single-base mismatches flanked by A·T bps showed equal or better efficiency of RecA binding than when the mismatches were flanked by G·C bps. Among the eight possible mismatches flanked by A·T bps, the A·C, A·A, G·A and C·C mismatches promoted RecA protein binding in presence of ATPγS. Interestly, an A·C mismatch flanked by A·T bps in a 28 bp DNA faciliated the binding of RecA protein to the same high level as when the 28 bp DNA contained a four-base cytosine bulge (Figure 4c). Chemical probing techniques were used to examine the structure of DNA within the RecA filament. It was found that upon binding of RecA protein, the DNA helix became accessible over at least 14 bp and the degree of chemical modification agreed with the binding efficiency of RecA protein (Figure 5).[48]

2.4 Summary

Gel electrophoretic studies have shown that DNAs containing 1–4-base bulges exhibit decreased mobilities in polyacrylamide gels, suggesting that bulged bases produce a kink in the DNA helix. The degree of kinking depends on the number of bases in the bulge, the base composition of the bulge, and the flanking bps. Visualization of a DNA containing a three-base bulge by EM has directly demonstrated kinks created by bulges and provided a measure of the distribution of the kinking angles. The binding of RecA protein to short DNAs containing lesions provides a sensitive means to detect perturbations in the helix. Binding of RecA protein to bulged DNA is influenced by the conformation of the bulged bases and by the kinking angles, which in turn are determined by the type and number of bases in the bulge. Although a single-base mismatch does not produce a kink in the DNA helix, we have found that certain single-base mismatches, for example an A·C mismatch flanked by A·T bps, facilitate the binding of RecA protein with the same high level as a four-base cytosine bulge. When these DNAs containing mismatches or base bulges were probed with chemicals, the degree of chemical accessibility agreed with the binding efficiency of RecA protein.

These studies provide critical structural information about DNAs containing bulges and mismatches. It will be important to correlate the structural information of these damaged DNAs with the relative rates of their correction by the methyl-directed mismatch repair system. Further, the binding of RecA to damaged DNA may facilitate recombinational repair by increasing the local concentration of RecA protein at the site of the damage. Therefore, the efficiency of RecA binding should also be taken into consideration in the overall repair/mutagenesis outcome of these damaged DNAs.

Figure 4 Comparison of RecA binding to bulged and mismatched DNAs. (a) Sequences of DNAs containing eight possible mismatches (positions indicated by X·Y) with two different flanking bps (A·T or G·C) and the control DNA (the lower sequence) are shown. (b) The 40 min time points of RecA binding to all 16 mismatched DNAs and the control DNA. The solid bars refer to mismatches flanked by G·C bps and the hatched bars to mismatches flanked by A·T bps. (c) DNAs containing: one-base cytosine bulges (C1), four-base cytosine bulges (C4), A·C mismatch flanked by A·T bps (A·C), G·T mismatch flanked by A·T bps (G·T), and the control DNA were compared using the filter binding assay as in Figure 3.

Figure 5 Diethyl pyrocarbonate (DEP) probing of DNAs containing A·C mismatches. DNAs containing an A·C mismatch flanked by A·T bps (lanes 1 and 2) or flanked by G·C bps (lanes 3 and 4) and the control DNA (lanes 5 and 6) were incubated without RecA protein (lanes 1, 3 and 5) or with RecA protein (lanes 2, 4, and 6) for 40 min at 37 °C. DEP was added at 37 °C for an additional 10 min and the modified DNAs were cleaved with piperidine and analyzed by electrophoresis in a 20% polyacrylamide–8.3 M urea gel. The positions of the ^{32}P label (∗), mismatched bp (boxed) and DEP-cleaved adenines (underlined) are indicated. In the autoradiogram, the mismatched adenines are indicated by arrows and a G-specific cleavage reaction of the control DNA serves as markers (M).

3 TRINUCLEOTIDE REPEATING DNA, NUCLEOSOME POSITIONING, AND HUMAN GENETIC DISEASES

DNA in the human cell is packaged progressively beginning with the most elementary particle termed the nucleosome. In a nucleosome 146 bps of DNA are wrapped 1.75 times around a protein core consisting of an octamer of the core histones (H2a, H2b, H3, H4). Each nucleosome is spaced in the human cell by ~50 bps of linker DNA to which histone H1 and other factors bind. This ''string of beads'', folded into larger structures by the action of H1, is eventually condensed into the metaphase

chromosomes observed by light microscopy. Different DNA sequences have been found to show differences in their affinity for wrapping around the core histone octamer and thus to be assembled into chromatin.

The ability of a variety of DNA sequences to form nucleosomes has been studied extensively. Repeated tracts of 4–6 adenines in-phase with the helix produce sequence-directed bends, and bent DNA preferentially assembles into nucleosomes,[49,50] presumably owing to the greater ease of wrapping of the DNA about the histone core. The sequence element $(A/T)_3NN(G/C)_3NN$ creates an anisotropically flexible wedge which also facilitates wrapping DNA about the histone octamer.[51] The 5S RNA gene from several species contains such flexible wedges and exhibits very strong sequence-directed nucleosome positioning.[52–55] Indeed, Shrader and Crothers[51] were able to create synthetic nucleosome positioning elements in which nucleosome formation was energetically favored over the 5S DNA by spacing up to 10 wedges in-phase with the helix.

Sequences also exist that inhibit nucleosome formation and in vivo such sequences, were they to occur in promoter or enhancer regions, could play an extremely important role in maintaining access to the DNA. DNA–RNA hybrids,[56] left-handed Z-DNA,[57] and DNA containing poly(dA : dT) runs have all been shown to exclude nucleosome formation in vitro.[58–60] Iyer and Struhl[61] found that poly(dA : dT) tracts in the yeast his 3 promoter stimulate Gcn4-activated transcription in vivo owing to nucleosome exclusion and increased accessibility of Gcn4-binding sites.

Described here are our findings that show that the expanded triplet sequences characteristic of DM and FraX, the two most common human triplet diseases, bracket the known range of affinities of DNAs for nucleosome assembly. While long tracts of repeating CTG triplets (expanded in DM) form the most stable known naturally occurring nucleosomes, long tracts of repeating CCG triplets (expanded in FraX) resist nucleosome assembly. In addition, methylation of the CCG repeats further represses the already weak ability of these (CCG) DNAs to assemble into chromatin. The physical basis for exclusion of nucleosomes by DNA containing long tracts of CCG repeats has been probed in experiments with model DNAs. Results from these studies revealed a new class of repeats in eukaryotic promoters, $[(C/G)_3NN]_n$, which may serve to loosen chromatin structure in the promoters of TATA-less genes.

3.1 CTG Repeats in Myotonic Dystrophy

DM is an autosomal dominant disease and the defect has been mapped to chromosome 19.[11,12] Two genes at the DM locus [the myotonic dystrophy protein kinase (DMPK) and the myotonic dystrophy locus-associated homeodomain protein (DMAHP) genes] have been shown to be affected by the expanded CTG repeat which is located in the 3′ untranslated region of the DMPK gene[62–65] and is about 1 kb from the major transcription start site of the DMAHP gene[66–68] (Figure 6). A block of 5–37 CTGs is frequently found in normal individuals, while DM patients with mild symptoms have triplet blocks of 50–80 repeats, and expansions from 100 to several thousand repeats can be found in individuals with full-blown symptoms. DM patients are heterozygous with only one of the two alleles containing an expanded triplet block, since homozygotes are rare and lethal. To date, the pathogenic mechanism of DM is not well understood.

Figure 6 Gene organization of the DM locus. The location of the translation start site (ATG), the translation stop sites (STOP), the putative poly(A) site (AATAAA), and the CTG repeats $[(CTG)_n]$ are indicated. The region demonstrating hypersensitivity to DNase I[69] is indicated by an arrow.

3.1.1 Nucleosome Positioning by Long CTG Repeats

Knowledge that the threshold for the triplet diseases frequently approximates the amount of DNA in a nucleosome, and the general understanding that any short repeating sequence may amplify sequence signals for nucleosome positioning or exclusion, led us[70] to examine the ability of long repeating tracts of $(CTG)_n$ to assemble into chromatin. This work was carried out using a simple but well established method of chromatin assembly involving mixing DNA with purified histone octamers (H2a, H2b, H3, H4) in 2 M NaCl followed by a progressive lowering of the salt concentration to 0.6 M or less by stepwise dilution or dialysis.[50,51,70–73] In the approach used in Wang et al.,[70] a minimal amount of histone octamers was used such that each DNA would on the average, contain only a single assembled nucleosome. This simplified measurement of the nucleosome position since the foreshortening due to multiple nucleosomes would have greatly complicated analysis. In this study, direct EM was utilized to measure the position of several hundred individual nucleosomes along single DNAs and the data were summed to create a nucleosome positioning map. To distinguish one end of the linear DNA from the other, one DNA end was labeled with a biotin–streptavadin tag.

Figure 7 (a) Scheme for nucleosome assembly on supertwisted plasmid DNA and end labeling with biotin–streptavadin complexes. (b) Visualization of nucleosomes assembled on streptavadin-labeled pSH2 DNA containing a $(CTG)_{130}$ repeat derived from DM patients. The DNA (curved filament) contains streptavadin protein bound to one end and one nucleosome assembled near the center of the DNA. In the absence of added histone, no nucleosome-like objects are observed. Reconstitution of the DNA with histones is described in this article. Preparation for EM including rotary shadowcast with tungsten was described by Wang et al.[70] Bar, 130 nm.

For such analysis it was important to also consider the effects of magnesium and supercoiling of the template DNA. Numerous DNA structural transitions are facilitated by negative supercoiling or influenced by heating in the presence of magnesium. A supertwisted plasmid, pSH2 isolated from *E. coli*, containing 130 CTG repeats derived from a DM patient was treated with magnesium and heat and then reconstituted into chromatin. The DNA was then linearized to place the CTG triplets in pSH2 between 32 and 43 map units along the DNA (Figure 7a and b). The resulting nucleosome map (Figure 8a) revealed that 48% of all the nucleosomes were present in the region between 30 and 45 map units. In contrast, the map for the Bluescript vector lacking the CTG insert (Figure 8b) showed a uniform distribution of nucleosomes over the length of the DNA with only 10% of the nucleosomes present in the region between 30 and 45 map units. The use of linear or supercoiled DNA that had not been treated with heat or magnesium still resulted in 29% of all nucleosomes localized to the triplet repeat (Figure 8c and d). Further analysis using a set of six pUC19-based plasmids (pretreated with heat and magnesium) containing 26–250 contiguous CTG triplet repeats showed that as the size of the triplet block increased in size the efficiency of nucleosome formation at the repeats also increased up to a repeat size of 180. These data are summarized in a normalized form in Figure 9.

These data provided the first direct evidence that repeating CTG triplets can serve as a strong nucleosome-positioning element. Indeed, this increase in strength of nucleosome formation occurred over the range where the triplet blocks change from normal, to the intermediate, to disease-causing. The EM observations therefore suggest that expanded blocks may create unusually stable nucleosomes that could alter local chromatin structure. Microscopy, however, was unable to provide precise measurements of the strength of the CTG repeat blocks as nucleosome positioning elements, data that would be essential to models based on these observations.

A method for measuring the strength of nucleosome positioning elements has been developed by Shrader and Crothers,[51] termed competitive nucleosome reconstitution (Figure 10a). In this assay, a small amount of the specific DNA to be tested (0.1 μg) is labeled with ^{32}P and then mixed with a 200-fold excess of unlabeled calf thymus DNA (20 μg) and ~5 μg of calf thymus histone octamers[50] in a solution containing 2 M NaCl. The salt is slowly lowered to 0.1 M NaCl and the mixture is electrophoresed on a 5% polyacrylamide gel to separate free DNA from the nucleosome-assembled DNA. The amount of DNA in each band is quantified. Usually three or four separate but identical experiments are carried out for each set of DNAs. In such studies, a sequence found in the *Xenopus borealis* somatic 5S RNA gene is frequently used as a standard against which other sequences are measured. This 5S element was previously the strongest

Figure 8 Distribution of nucleosomes reconstituted on to: (a) closed circular pSH2 DNA [which contains the $(CTG)_{130}$ repeat], (b) closed circular Bluescript vector, (c) linear pSH2 without magnesium and heat treatment, and (d) closed circular pSH2 without magnesium and heat treatment. Reconstitution and preparation for EM were performed as described.[70] At least 100 DNA molecules containing single nucleosomes were photographed and the position of each nucleosome from the streptavidin-labeled end was measured, and a histogram (length broken into 20 segments with each percentage of length being one map unit) showing the location of the nucleosomes along the DNA was generated. The filled bars indicate the position of the CTG repeat sequences along the DNA.

known natural nucleosome positioning element. Using this method, we[74] compared DNAs containing 75 and 130 CTG repeats to the *X. borealis* somatic 5S RNA gene. In such studies it is important that the DNAs being compared are of the same size. Thus two pairs of DNAs, ~285 and ~450 bp in size, were compared.

The results of such an analysis for the sets of DNAs of ~285 and ~450 bp are shown in Figure 10(b) and (c). The nucleosome-assembled DNA appears as a retarded band. One major retarded band was observed in both 5S RNA gene samples while two retarded bands were found in the ~285 bp $(CTG)_{75}$-containing DNA and possibly three closely spaced retarded bands were present in the ~450 bp $(CTG)_{130}$-containing DNA. The multiple retarded bands represent DNAs associated with two or three nucleosomes. The results revealed that the ratio of the fraction of the nucleosome-assembled DNA to free DNA is 5.6 ± 0.4-fold higher in the DNA containing the $(CTG)_{75}$ block as compared with the 5S RNA gene. The ~450 bp DNA containing the $(CTG)_{130}$ block is 8.7 ± 0.7 fold stronger than the 5S RNA gene (472 bp) in nucleosome assembly.

These assays allow one to calculate the free energy difference for nucleosome formation. The difference in

Figure 9 Strength of sequence-directed nucleosome positioning correlates with the size of the repeated CTG block. Data from Figure 3 of Wang et al.[70] were normalized as described.

free energy between the $(CTG)_{75}$ DNA and the 5S RNA gene was found to be 1015 ± 43 cal mol^{-1} and for the $(CTG)_{130}$ DNA the difference was 1276 ± 45 cal mol^{-1}. In Figure 11, these results are combined with data obtained by Shrader and Crothers[51] and further work described below. To match the different studies, the free energies for the vector DNA for each set of experiments was taken as zero.

These studies demonstrated that when CTG repeat blocks grow to sizes of $n \geq 75$ they become the strongest known natural nucleosome positioning elements, and (at $n = 130$) are nearly nine times stronger than the 5S element. The difference in binding free energy between the strongest and average DNA elements is seen to span a range of $\geq$100-fold. However, the total energy difference measured in high salt is relatively low, 3 kcal mol^{-1}.[70] Hence whether or not such differences measured in high salt would be physiologically relevant remained in question. In the cell, at physiological ionic strength and in the presence of histone H1 and nucleosome assembly factors, these differences could be great enough to dictate nucleosome positioning. The strongest evidence that these free energy differences do represent physiologically important differences was to come from model studies of the CCG triplet repeat from Fragile X expansions as described below.

Godde and Wolffe[78] also examined nucleosome assembly on $(CTG)_n$ repeats by competitive nucleosome reconstitution and mapped translational and rotational positions by nuclease and hydroxyl radical cleavage. They confirmed the observation of Wang and Griffith[74] that CTG repeats create sites for preferential nucleosome assembly. However, they did not observe the increase in efficiency of nucleosome assembly with increasing size of the repeat from 10 to 55 and 62 copies, which may be too short to display the effect. Probing of rotational position demonstrated a clear 10–11 bp repeating pattern over the DNA containing six copies of CTG repeat and the pattern remains similar in $(CTG)_{55}$ DNA. Moreover, the $(CTG)_6$-containing DNA favors a single translational position with the CTG sequence bordering the nucleosomal dyad whereas the $(CTG)_{55}$ DNA showed several nucleosome positions.

3.1.2 Implications of Arrays of Hyperstable Chromatin at the Myotonic Dystrophy Locus

The in vitro nucleosome reconstitution studies described above clearly show that repeating CTG triplets can generate very unusual chromatin structure. When the repeat tracts grow into the size range in which DM disease symptoms appear, these repeat tracts can generate chromatin segments with stabilities that are possibly nine times greater than the previously strongest known natural nucleosome positioning element, the 5S DNA. Although the precise physical reason why such repeating triplets generate such highly stable chromatin remains unclear, a number of possible biological implications of the appearance of such abnormally stable chromatin segments are worth mentioning.

Otten and Tapscott[69] have carried out in vivo mapping of nuclease hypersensitive sites with DNA samples of fibroblasts and myoblasts from three unrelated DM patients in which the DM alleles are heterozygote and the expansion is ~6 kb. Compared with the observations from an unaffected individual and the wild-type allele, the expanded allele showed loss of the DNAse I hypersensitive site located just 3′ of the CTG repeat (indicated by an arrowhead in Figure 6) and resistance to restriction endonuclease cleavage adjacent to the DNase I hypersensitive site. Recently, this hypersensitive site has been mapped to an enhancer region which regulates the expression of the DMAHP gene.[79] In cells of DM patients with a loss of the hypersensitive site, the amount of DMAHP transcript was reduced compared with the controls and the amount of transcript from the expanded allele was also greatly lowered compared with that from the wild-type allele. These results elegantly demonstrated that the expanded CTG repeat produces an altered chromatin structure, possibly resulting from the strong nucleosome positioning by the CTG repeat. The altered chromatin structure might suppress the transcription of the DMAHP gene which leads to the pathogenesis of DM.

Furthermore, the appearance of a segment of hyperstable chromatin could in itself promote further expansion

Figure 10 Competitive nucleosome reconstitutions with CTG triplet containing DNA. (a) Scheme for competitive nucleosome reconstitution. (b) The ~285 bp $(CTG)_{75}$-containing fragment or the 303 bp 5S RNA gene and (c) the ~450 bp $(CTG)_{130}$ DNA or the 472 bp 5S RNA gene labeled with ^{32}P (100 ng) were mixed with 20 μg of unlabeled calf thymus DNA and ~5 μg of calf thymus histone octamers in a solution containing 2 M NaCl, 100 μg mL^{-1} of bovine serum albumin and 0.1% Nonidet P-40. The total DNA added is about a 4-fold molar excess over the histone octamers. The salt was slowly lowered and the mixture then electrophoresed on a 5% polyacrylamide gel. Samples were visualized by autoradiography.

of the triplet tract. During the replication of eukaryotic DNA, the replication machinery must remove the DNA template from the histone octamer prior to, or possibly in concert with, the helicase action that separates the two DNA strands. Were the replication machinery to be severely hindered in this action by the presentation of an array of hyperstable nucleosomes, then the likelihood of polymerase slippage as the replication fork transited the triplet tract would be expected to be much greater.

As arrays of hyperstable nucleosomes might impede the replication machinery, they might also slow or stop

Figure 11 Comparison of free energies derived from several nucleosome positioning sequences. Data which are at the left of the free energy scale bar were adapted from Shrader and Crothers.[51] The sequence of the 20 bp anisotropically flexible wedge is TCGGGTTTAGAGCCTGTAAC. Results from studies of Wang and Griffith[74–77] are listed at the right side of the bar with the free energies of the vector DNA (pUC19 fragments) defined as zero cal mol^{-1}.

transcription complexes. When RNA polymerase stalls on DNA the nascent RNA chain is frequently cleaved, inactivating the RNA. Examination of transcription of the DMPK gene has provided conflicting results regarding the amount of DMPK transcript expressed by the expanded DM allele.[80–86] Whether or not expanded CTG tracts in DM protein kinase gene result in lowered mRNA levels is currently in question. It is possible that such an effect may only be evident when the tracts become longer than those investigated in some of the studies reported to date.

Finally, a global effect of arrays of hyperstable nucleosomes may be to generate domains of inactive chromatin. Such elements could inactivate genes either upstream or downstream of the domain and possibly over distances of many kilobases. Domains generated by an array of hyperstable nucleosomes would be similar to chromatin barriers that have been shown to silence genes moved into their proximity. Given the findings that the CTG tract in the DMPK gene is also in the upstream region of the DMAHP gene,[79,87] this presents one of the most attractive models of how this expanded CTG tract could exert its biological effect. It could be imagined that as the CTG tract grows, the size and thus strength of the array of hyperstable nucleosomes increase greatly and with each additional nucleosome added the effect of this very unusual hyperstable chromatin boundary could grow from just interference with transcription of the DMAHP gene to interference also with the DMPK gene and finally to interfering with all three genes including the upstream 59 protein gene. The clinical observations that the presentation of DM differs depending on the size of the CTG tract may reflect a progressive involvement of additional genes as the tract increases in size.

3.2 Expanded CCG Repeats in Fragile X Syndrome and Folate-sensitive Fragile Sites

Fragile sites are chromosomal loci that stain poorly, contain gaps and are frequent sites of DNA strand breakage. Thus they represent regions of unstable chromatin structure. More than 100 separate fragile sites have been identified in the human genome, classified as common or rare, and, further, they are divided according to the agents used to identify them.[88] Fragile sites are highly conserved and appear to have played key roles in the stepwise evolution of primate chromosomes. Recent work suggests that they are major sites of drug-induced chromosomal amplification.[89] A number of fragile sites have been cloned, the majority being members of the class termed rare, folate-sensitive sites which are seen

by light microscopy when cells are exposed to a folate starvation regime. Sequence analysis of five rare, folate-sensitive sites, FRAXA, FRAXE, FRAXF, FRA16A, and FRA11B, revealed long blocks of repeating CCG triplets together with the frequent methylation of nearby CpG islands.[90–96] Another fragile site, FRA16B, was sequenced and found to involve a highly A/T-rich element demonstrating that not all fragile sites involve repeating CCG triplets. Expansion of the triplet block in the 5′ untranslated region of the FMR-1 gene[97,98] at FRAXA from 20 to 50 repeats in most individuals to >200 CCG repeats has been linked to the FraX (see below). The expanded triplet block is the site of preferential breakage at FRAXA.[90,91] The FRAXE site on the X chromosome[93] is correlated with a rare form of mental retardation, and the FRA11B site is associated with Jacobsen's syndrome. Here, a portion of the long arm of chromosome 11 is lost, implying a link between this fragile site and chromosome breakage.[96] FRAXF and FRA16A are apparently without disease phenotype.[94,95]

FraX was named for the presence of a rare, folate-sensitive fragile site on the X chromosome (FRAXA) whose appearance correlates with the disease,[97,98] In contrast to DM, the FMR-1 gene is likely the only gene

Figure 12 Distribution of nucleosomes assembled on closed, circular (a) pRW3376 containing the $(CCG)_{76}$ repeat block and (b) pT7 blue vector as a control; (c) $p(CCGNN)_{48}$ plasmid and (d) pGEM3zf(+) vector as a control. Nucleosome assembly and EM analysis were performed as described.[75,76] At least 100 DNA molecules containing single nucleosomes were photographed, the position of each nucleosome from the streptavidin-labeled end (filled circle) was measured, and a histogram was generated (with DNA length broken into 20 slices and each percentage of length equivalent to 1 map unit) showing the location of the nucleosomes along the DNA. The positions of the $(CCG)_{76}$ sequence in pRW3376 and the $(CCGNN)_{48}$ sequence in $p(CCGNN)_{48}$ are indicated.

involved in FraX. Studies of the FMR-1 gene have also shown reduced transcription from this locus in FraX patients[99] and rare FraX cases are seen in which there has been a deletion or point mutation in the FMR-1 protein, pointing to loss of protein function as a cause of the disease.[100] Moreover, the severity of the disease has been shown to be directly related to the size of the triplet repeat and also the purity of the repeat tract. Thus, moderate-sized pure CCG repeat tracts are more deleterious than longer repeat tracts containing interruptions. Finally, there is also a strong correlation between the severity of the disease symptoms and the level of methylation of the region. Hence any model for the molecular basis of FraX will have to account for these observations.

3.2.1 Nucleosome Exclusion by Repeating CCG Tracts

The discovery of hyperstable nucleosome formation by long tracts of CTG triplet repeats spurred a parallel analysis of DNAs containing long CCG triplet repeat tracts. This work was further impelled by the knowledge that the fragile sites containing CCG triplet blocks exhibit properties of unstable chromatin suggesting that significant effects on chromatin structure due to the presence of these repeats might be found. Indeed it had been speculated earlier[101] that fragile sites may result from the inability of DNA to fold compactly during metaphase.

In the work of Wang et al.,[75] a series of plasmids containing different sized tracts of repeating CCG triplets were employed. The plasmid pRW3376 contains 76 tandem CCG repeats[102] and this DNA was reconstituted with purified histone octamers, linearized, and one DNA end labeled with streptavadin to place the $(CCG)_{76}$ repeat block between 18% and 26% from the marked end in a manner similar to that illustrated in Figure 12(a). A nucleosome map was then prepared. Inspection of the data showed that only 2.6% of the DNAs had a nucleosome located between 15 and 20 map units from the marked end and no molecules had nucleosomes between 20 and 25 map units. This was in contrast to other segments of 5 map units length which showed from 5% to 10% of the DNA with nucleosomes assembled. The parent vector showed no regions of nucleosome exclusion (Figure 12b). These direct EM observations provided the first evidence that repeating CCG triplets could lead to nucleosome exclusion in contrast to nucleosome positioning observed with repeating CTG triplets. Control experiments showed that legitimate nucleosomes were being formed on normal sequence DNA in the same reactions.

Competitive nucleosome reconstitution was then used in this study to measure the energetics of nucleosome formation for DNA fragments containing CCG repeats of increasing size (Figure 13a and b). The ratio of nucleosome assembled DNA to free DNA for a pUC19 fragment and similar length fragments containing 10, 24, 54, and 76 CCG repeats was determined. It was found that as the length of the repeat block increased, the efficiency of nucleosome assembly decreased. Whereas a 261 bp DNA containing 10 tandem CCG repeats showed a 1.4-fold lower efficiency (30% decrease) in nucleosome assembly relative to the pUC19 fragment, the fragment containing 76 tandem CCG repeats was 2.6 ± 0.4-fold less effective (62% decrease), corresponding to a $564 \pm 89\,\text{cal mol}^{-1}$ difference in free energy (Figure 11). Compared with the free energy value for a similar sized DNA containing 75 CTG repeats (see above), this amounts to a 40-fold difference between the two repeating triplet DNAs. These observations clearly paralleled the in vivo observation of fragile sites being regions of unstable chromatin.

While the physical basis for repeating CTG triplets forming hyperstable nucleosomes remains unclear, experiments with model variants of the CCG motif provided clues as to why this expanded triplet may exclude nucleosomes and, further, revealed a possible function for these motifs in eukaryotic genomes.

3.2.2 Model Studies Involving the Repeat $[(C/G)_3NN]_n$

Considering of the properties of the sequence motif in the 5S RNA gene, $(G/C)_3NN(A/T)_3NN$, which forms very strong nucleosomes,[51,103] we postulated[76] that DNA containing long repeats in the form of $(G/C)_3NN(G/C)_3NN$ might exclude nucleosomes. This latter motif differs from the 5S RNA gene element in that each time minor groove compression is required, the DNA presents the histone octamer with a wedge that favors bending into the major groove. Shrader and Crothers[51] had noted that a triplet of As or Ts preferentially bends into the minor grove of DNA whereas a triplet of Gs or Cs bends preferentially into the major grove. Thus DNA containing a nucleosome-sized tract of repeating CCGNN pentanucleotides which is a member of the $(G/C)_3NN(G/C)_3NN$ motif family should resist nucleosome formation. Pure repeating CCG triplet tracts are also a member of this general family and if nucleosome exclusion were observed for DNA containing repeating CCGNN pentanucleotides this would provide an explanation for nucleosome exclusion by repeating CCG triplets.

To test the hypothesis that long tracts of $(G/C)_3NN$ repeats will exclude nucleosomes, three pGEM3zf(+)-based recombinant plasmids, $p(CCGNN)_{12}$, $p(CCGNN)_{24}$, and $p(CCGNN)_{48}$ containing, respectively, 12, 24, and 48 tandem copies of the CCGNN repeat with the Ns varied and rich in As and Ts, were generated. EM was then utilized together with in vitro nucleosome reconstitution onto supertwisted $p(CCGNN)_{48}$ plasmid

Figure 13 Competitive nucleosome reconstitution with (a, b) CCG and (c, d) CCGNN containing DNAs. (a) Autoradiogram of a competitive nucleosome reconstitution experiment. Lane 1, the 262 bp pUC19 fragment; lanes 2–5, DNA fragments containing 10, 24, 54, and 76 CCG repeats respectively. Note: the $(CCG)_{54}$ and $(CCG)_{76}$ repeat blocks contain AGG and CAG interruptions.[102] (b) Dependence of nucleosome assembly on the length of the repeat block. (c) Autoradiogram of a competitive nucleosome reconstitution experiment. Lane 1, the 262 bp pUC19 fragment; lanes 2–4, DNA fragments containing 12, 24, and 48 CCGNN repeats, respectively. (d) Dependence of nucleosome assembly on the length of the repeat block. DNA preparation, reconstitution of the fragments with histones, and gel electrophoresis were as described elsewhere.[75,76] Each DNA was reconstituted in three separate but identical experiments, and the fraction of DNA in the nucleosome-assembled and nucleosome-free DNA bands was measured by a PhosphorImager.

DNA to examine the propensity of the inserts to assemble into nucleosomes as described above. Subsequent to assembly the DNA was linearized placing the CCGNN block in $p(CCGNN)_{48}$ between 27% and 34% from the tagged end. Analysis revealed strong nucleosome exclusion over the $(CCGNN)_{48}$ insert with only 2% of all nucleosomes mapped located between 25 and 35 map units whereas in other segments of this length ~10% or more of the DNA contained a nucleosome (Figure 12c). In contrast, the parent pGEM3zf(+) vector showed no regions of strong nucleosome exclusion (Figure 12d).

Competitive nucleosome reconstitution assays were then employed as described[74] to quantify the degree of nucleosome exclusion over the insert in these plasmids. DNAs ~260 bp in length containing $(CCGNN)_n$ blocks of 12, 24, or 48 repeats were generated. As the length of the CCGNN repeat sequence increased from 12 to 48 repeats within a ~260 bp segment, the ability of the DNA to exclude nucleosomes increased in proportion to the length of the repeat block (Figure 13c and d). Analysis showed that the 268 bp DNA containing the $(CCGNN)_{48}$ repeat is 4.9 ± 0.6-fold less efficient in nucleosome assembly than the same sized pUC19 fragment. Indeed,

a 261 bp DNA containing 12 tandem CCGNN repeats assembled nucleosomes 94% as efficiently as a 262 bp pUC19 fragment. When these results were combined with results from earlier studies, it was estimated that the $(CCGNN)_{48}$ repeat block is ~78-fold less efficient than a similar length block of repeating CTG triplets. The difference in free energy between the $(CCGNN)_{48}$ fragment and the pUC19 DNA is 937 ± 79 and $\sim 2600\,cal\,mol^{-1}$ relative to the CTG_{75} repeating element (Figure 11).

Based on the findings described above, a computer search was carried out using the GenBank database to examine the prevalence of the general $[(G/C)_3NN]$ motif.[76] Searches against 240 bp of a $[(G/C)_3NN]_{48}$ continuously repeating sequence revealed many matches, and 75 examples showed ≥85% sequence match over 200 bp of this motif (Table 2). Many of these were present in or near the control regions for eukaryotic genes. Of the 75 with the greatest number of sequence matches, 31 genes were noted to contain the $(G/C)_3NN$ motif in the 5′ region upstream of the coding sequences. Such regions would be loci where nucleosome exclusion would be expected to provide favored access to sequence-specific proteins engaged in the regulation of gene expression. It was also observed that at least 20 of these 31 genes lack a TATA box in the promoter region and are "TATA-less" genes. In two of these genes, the 5′ regions have been mapped for nuclease hypersensitive sites. The −530 to −300 nucleotide (nt) upstream control region of the human dihydrofolate reductase gene contains the $[(G/C)_3NN]_{48}$ motif (with 87% sequence match) and this overlaps with a hypersensitive region mapped in vivo.[104] In the gene for the human ETS-2 nuclear phosphoprotein, there is a sequence upstream of the gene between nts

Table 2 Examples of genes containing regions showing >85% sequence matches to the $[(G/C)_3NN)]_{48}$ sequence taken from a GenBank search[a]

Location	Gene or encoded protein	Sequence matches[b]
5′ end (upstream of coding sequences)	Human glutamate dehydrogenase	222/235
	Human arginosuccinate lyase	213/230
	Human insulin receptor	214/237
	Wheat α-amylase	208/233
	Chicken hsp 90	205/231
	Human dihydrofolate reductase	205/228
	Pig nuclear factor 1	201/225
	Rat insulin-like growth factor binding protein	202/232
	Rabbit metallothionine	195/229
	Mouse neu proto-oncogene	222/236
	Human hematopoietic cell-specific protein	215/235
	Human fibronectin	205/233
	Rat phosphorylase kinase catalytic subunit	199/230
	Human vitronectin protein	196/229
	Mouse S16 ribosomal protein	202/232
	Rat neu oncogene	214/231
	Human gastrin releasing peptide	202/228
	Human ETS 2 oncogene	204/231
	Rat nucleolin	199/230
Coding region	Chicken c-fos proto-oncogene	208/231
	Chicken tropoelastin	206/224
	Human collagen-like protein	201/217
	Herpes simplex 1 UL 18	204/230

	Human thymidine kinase	199/233
	Chicken ubiquitin	202/231
	Human translocation fusion protein (E2A-Prl)	202/232
	Human p120	199/233
3′ end (downstream of coding sequences)	Human cytochrome p450	207/232
	Mouse histone H2A·X	209/235
	Human lamin B2	206/232
	Chicken p53 oncoprotein	193/215
	Human α_1 collagen type 1	204/232

[a] At least 75 genes in the GenBank were found to have ≥85% sequence matches to $[(G/C)_3NN]_{48}$.
[b] The first number indicates the number of bases showing sequence matches with $[(G/C)_3NN]_{48}$ and the second number refers to the length of this sequence.

−195 and +45 containing the $[(G/C)_3NN]_{48}$ motif (with 86% sequence match). The promoter region of this gene maps between nts −159 and +141. Here studies of nucleosome positioning in the promoter region using S1 nuclease revealed a hypersensitive region from nts −150 to −50.[105] This 100 bp hypersensitive region exactly co-maps with the region containing the $[(G/C)_3NN]_{48}$ motif.

The discovery of long DNA sequences in the human genome with strong matches to the $[(G/C)_3NN]_n$ motif and the finding that in two cases these sites correspond to regions shown by others to be spared of nucleosomes have several important implications. First, it provides the most compelling evidence to date that the differences in free energy measured in vitro in high salt (which are in the range of a few kilocalories) are biologically significant. Indeed, the two most common human triplet diseases, DM and FraX, involve triplet expansions which bracket the range from strongest to weakest nucleosome assembly elements. The second and broader implication of this work is that the sites composed of long repeats of $(C/G)_3NN$ pentanucleotides present in the 5′ control regions of genes lacking TATA boxes may be a common occurrence in eukaryotic genomes. Here these elements would serve to loosen the chromatin structure, providing access to the DNA for the transcriptional machinery.

In FraX, AGG interruptions have been shown to stabilize the CCG repeats against expansion.[106–111] Comparison of the data presented in the papers of Wang and Griffith (Figure 13a–d),[76] reveal a greater resistance to nucleosome assembly for the $(CCGNN)_{48}$ DNA in contrast with the similar sized $(CCG)_{76}$ block. This suggests that the interruptions in the latter DNA may significantly impair the ability of this overall element to exclude nucleosomes. Thus the well characterized effects of these interruptions could be to moderate the ability of these long repeat blocks to alter the local chromatin structure.

3.2.3 *Methylation of CCG Enhances Nucleosome Exclusion*

In eukaryotic cells, methylation of CpG dinucleotides by DNA methyltransferase has been found to inhibit directly gene expression.[112] This enzyme places a methyl group at C-5 of the cytosine residues of 5′CpG3′ dinucleotides and has been shown to play an important role in embryonic development.[113] Repression of genes by DNA methylation has been studied extensively[112] and might serve as a regulatory step to turn off a gene in order to distinguish alleles of different parental origins (genomic imprinting), or when a gene is not needed, or is subject to dosage compensation (X chromosome inactivation). The inhibition of transcription by methylation may be mediated by the binding of a methyl-CpG binding protein to DNA sequences containing methylated CpG dinucleotides.[114,115] In the context of FraX, Sutcliffe et al. have demonstrated that long CCG repeats alone cannot repress FMR-1 transcription whereas DNA methylation is required for transcriptional repression of the FMR-1 gene.[116] Furthermore, DNA demethylation by 5-azadeoxycytidine has been shown to reactivate the FMR-1 gene in patient cell lines.[117] These observations prompted studies to determine how methylation of the CCG tracts would influence their already poor ability to assemble into chromatin.

SssI methylase was used in our studies[77] to place a methyl group on the C-5 position of cytosines within the 5′CpG3′ dinucleotides. Two sets of experiments were carried out in this study. In one, a 262 bp fragment from pUC19 was compared with a 282 bp DNA containing 76 tandem CCG repeats. In the second, the same pUC19 fragment was compared with a 268 bp fragment containing 48 contiguous CCGNN repeats as described above. The number of possible methylation sites for the pUC19 fragment, the CCG-containing DNA, and the CCGNN-containing DNA is 40, 164, and 102, respectively. Here the level of methylation was estimated from the cleavage pattern by the methylation-sensitive restriction endonuclease HhaI. Competitive nucleosome reconstitution was then used to measure the energetics of nucleosome formation over the CCG and CCGNN repeats as compared with a pUC 19 DNA of the same size. This analysis (Figure 14a–c) showed that DNA methylation had no measurable influence on nucleosome formation for the pUC 19 fragment, an observation noted in several previous studies.[118–120]

In contrast, the $(CCG)_{76}$ DNA methylated at 85% of the available sites was 2.0 ± 0.2-fold less effective in nucleosome assembly compared with the same $(CCG)_{76}$ DNA fragment that was unmethylated, and 4.4 ± 0.4-fold less effective relative to the pUC19 fragment. The difference in free energy between the methylated (at 85%) and the unmethylated $(CCG)_{76}$ DNA is 405 ± 44 cal mol^{-1}. With respect to the pUC19 DNA, the methylated (at 85%) $(CCG)_{76}$ DNA is 880 ± 54 cal mol^{-1} less favorable (Figure 11). Similar results were obtained when the pUC19 fragment was compared with the 268 bp fragment containing 48 tandem CCGNN repeats. The $(CCGNN)_{48}$ DNA fragment methylated at 62% of the available sites was 2.1 ± 0.3- and 12.6 ± 1.6-fold less effective in nucleosome formation compared with the unmethylated $(CCGNN)_{48}$ DNA and the pUC 19 fragment, respectively (Figures 11 and 14b). These efficiencies correspond to 425 ± 93 and $1498 + 75$ cal mol^{-1} differences in free energy, respectively. The greatest difference was observed with a fragment

Figure 14 Competitive nucleosome reconstitution with methylated DNAs. Competitive nucleosome reconstitution was carried out comparing (a) a 262 bp pUC19 fragment with a 282 bp DNA containing 76 tandem CCG repeats at three different levels of methylation. Lanes 1–3, the pUC19 fragments methylated at 0, 95, and ~100% of the available sites respectively; lanes 4–6, the $(CCG)_{76}$ DNA fragment methylated at 0, 45, and 89% of the available sites respectively. (b) Comparison of the 262 bp pUC19 fragment to a 268 bp DNA containing 48 tandem CCGNN repeats at three different levels of methylation. Lanes 1–3, the pUC19 fragments methylated at 0, 36, and 43% of the available sites respectively; lanes 4–6, the $(CCGNN)_{48}$ DNA methylated at 0, 12, and 62% of the available sites respectively. (c) Dependence of nucleosome assembly on methylation of CpG dinucleotides. Data from the competitive nucleosome reconstitution experiments are shown. Each DNA was reconstituted in three separate but identical experiments, and the fraction of DNA in the nucleosome-assembled and nucleosome-free DNA bands was measured by PhosphorImager scanning.

containing the $(CCGNN)_{48}$ repeat block. When this DNA was highly methylated, it was nearly 13-fold less effective in nucleosome assembly compared with a mixed sequence DNA of the same size.

Wang and Griffith[77] presented a general model for the role of CCG repeats and methylation in the generation and expression of fragile sites containing these triplet repeats. It was proposed that long repeating CCG triplet blocks inhibit chromatinization of DNA which would increase the accessibility of these regions to DNA methyltransferase. Next, methylation of the repeats would further repress chromatinization and make the DNA more available for binding by methyl CpG binding proteins which have been shown to repress transcription. The net effect of these changes would be the expression of the fragile site and the genetic repression of nearby genes such as the FMR-1 gene.

Godde et al.[121] also examined the ability of CCG repeats to assemble into nucleosomes and found that DNA containing a short CCG repeat (13 copies), upon methylation, showed preferential nucleosome assembly with an affinity similar to that of the $(CTG)_{10}$-containing DNA. However, in a longer CCG DNA (74 copies), methylation represses the ability to assemble nucleosomes to a level similar to mixed sequence DNA. However, the mechanism for the different effects of

methylation and repeat number on nucleosome assembly is not clear.

3.3 Summary

The expanded CTG and CCG triplets were shown to generate nucleosomes with extremely unusual properties. We have demonstrated that DNAs containing 130 copies of CTG repeats assemble into nucleosomes with a stability nine times higher than any previously known natural DNA element. Moreover, expanded CCG repeats show nucleosome exclusion and methylation of the CCG repeats further enhances this exclusion, providing a possible molecular explanation for the basis of fragile sites in chromosomes. Finally, a DNA motif $(CCGNN)_n$, based on the CCG repeat, excludes nucleosomes in vitro and is a DNase I hypersensitive site in yeast (unpublished data).

These findings provide us with a hypothesis in which expanded CTG and CCG triplets result in chromatin with unusual properties which can cause harmful biological effects including the generation of fragile sites and alteration of gene expression. Further, studies of the effect of these simple repeats in forming chromatin and, in the future, the ability of such templates to be replicated or transcribed will contribute greatly to our knowledge of the role of chromatin structure in fundamental biological processes.

ACKNOWLEDGMENTS

I express my deepest appreciation to Dr Jack D. Griffith for his support. Most of the work described here was carried out in his laboratory.

ABBREVIATIONS AND ACRONYMS

ATPγS	Adenosine-5′-*O*-(3-thiotriphosphate)
bp	Basepair
CF	Cystic Fibrosis
DEP	Diethyl Pyrocarbonate
DM	Myotonic Dystrophy
DMAHP	Myotonic Dystrophy Locus-associated Homeodomain Protein
DMPK	Myotonic Dystrophy Protein Kinase
EM	Electron Microscopy
FraX	Fragile X Syndrome
NMR	Nuclear Magnetic Resonance
nt	Nucleotide
PCR	Polymerase Chain Reaction

Three-dimensional (3-D) structures at the molecular level of chromosomes and other cell structures are far beyond the reach of ordinary or confocal (3-D) light microscopy (LM). The electron tomography method (ETM), i.e. transmission electron microscopy (TEM) tomography, is able to provide methods of 3-D reconstruction of macromolecular assemblies, providing insights into the qualitative and quantitative spatial comprehension of macromolecular structures. ETM is a powerful method for developing reliable immunoelectron tomography (IET) and in situ hybridization analysis at the molecular level.

With ETM the data are collected with TEM by taking tilt series, i.e. projection images from different viewing angles over the object. By combining such projections taken over a sufficient angular range (from 0 to $\pm 60^{\circ}$ manually, e.g. in 3° increments), a wholly transparent 3-D representation of the object is recovered with necessary details. This requires the use of suitable computational methods.

Automatic single-axis tilt-series data registration is possible today that will not only allow the collection of data with increments as small as 1°, for high-resolution reconstructions of bulky whole mounts, but will also protect the specimen from electron beam damage (dose reduced by a factor of 10–100). Only automation of ETM procedures makes it possible to collect tilt series of cryo-electron microscopy (EM) preparations of unfixed and unstained preparations in vitrified ice, i.e. fully hydrated samples close to the native state.

Novel methods and tools for electron tomography are available that have been developed in different laboratories. Our electron tomography programs are automated to a high degree and therefore very fast and easy to use, in comparison with other program kits that are available. Specifically, our arsenal includes advanced tomography procedures based on the maximum entropy method (MEM) (e.g. 16-bit gray-scale MEM).

A collection of preparative methods for preserving whole-mounted chromosomes and cells for ETM studies has been developed. Examples of 3-D reconstructions of human chromosomes are shown at high resolution (3–15 nm).

It is considered that ETM allows 3-D reconstructions, depending on the thickness of the preparation, with a

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

resolution in the range 2.5–8.5 nm. In this respect, some success was recently made as we were able to detect nanoprobes (1.4-nm immunogold markers) with the IET methods developed.

ETM of chromosomes involving localized genes with in situ hybridization and gold-labeling techniques is possible and would allow chromosome mapping in a 3-D configuration with molecular resolution much more accurately than any standard EM method which are affected by superimposing gold labels with their accompanying structures.

Concerning the structure and folding of the DNA in chromosomes, it is important to note that the linear sequence of bases in DNA is accompanied by higher level organizations, composed of loops, twists and folds in the long DNA chain, and, significantly, by DNA–protein interactions, e.g. nucleosomes, supranucleosomes, together with telomerase, topoisomerases and the new scaffold proteins [structural maintenance of proteins (SMC) family] recently described. These so-called 'higher order structures' are certainly very much involved in the regulation of gene expression in chromosomes. Further, it is easy to realize that genes distantly located in the linear sequence map could in fact be topologically associated when DNA is folded in chromosomes, and thus mutually regulated. Sequencing of the genomes does not include and cannot reveal higher order structures. It is only with ETM that genome maps can be brought in relation to 3-D molecular configurations, and it can be refined by combination with in situ hybridization to localize gene sequences and with IET to identify chromosomal proteins.

1 INTRODUCTION

1.1 Chromosome Structure

Higher order chromosome structure is an enigmatic and challenging problem. It is more than 100 years since the word chromosome first appeared in the literature,[1] and almost 50 years since the principle of the DNA structure was established.[2] The discovery of DNA structure was a turning point in biology and initiated the rapid development of molecular biology. We have been treated to detailed descriptions of various biological structures at the molecular level and various roles have been attributed to DNA. As for DNA, the overall principle of replication is clear, but many details even of replication have turned out to be uncompromisingly complex.[3] In addition, the organization of DNA and the regulation of its function in interphase nuclei and its condensation into metaphase chromosomes at mitosis remain a distressing tangle in cell biology.

Difficulties in solving chromosome structure largely stem from the huge amount of DNA wrapped into chromosomes. Yet the packing and organization of the DNA in many phages and viruses with basically less DNA are also unclear.[4] The length of DNA per diploid human somatic nuclei (diameter about 5–10 μm) is about 1.8 m. In mitosis twice as much is arranged into 46 chromosomes with a total length of about 200 μm. Consequently, the compaction proportion of the DNA in chromosomes is about $10^4 : 1$.[5]

In addition, the length and thickness of the chromosomes change dynamically when chromosomes condense in mitosis. Related changes are observed in meiosis, although the chromosomes are more attenuated and delicate, forming the so-called synaptonemal complexes when chromosomes pair up. In mitosis, early prophase chromosomes appear as long strands that reach full compression at metaphase. After mitosis, the chromosomes revert to their diffuse interphase form. In the interphase nucleus, chromosome positions tend to be conserved in their anaphase–telophase configurations. In this orientation, called the Rabl orientation,[6] centromeres and telomeres occupy opposite regions of the nucleus. The chromosomes somehow rearrange themselves before the next division. Regions of interphase chromosomes, in yeast and *Drosophila*, have recently been shown to be in Brownian motion limited to a subvolume no more than 1% of the total nuclear volume of living cells.[7]

What regulates, causes and lies behind the interphase chromosome movements and prophase contraction at the molecular level is not known, but such movements may be caused by proteins analogous to the contractile proteins of the cytoskeleton. Microtubules have not been observed, in higher eukaryotes, inside nuclei as long as the nuclear envelope (NE) remains intact. In lower eukaryotes, e.g. in yeast cells, bundles of microtubules are detected inside cell nucleus, at mitosis, as the NE remains intact in the budding. Bundles of striated microfilaments[8] have been described in meiosis along the lateral elements of the synaptonemal complex (SC) and shown by immunological methods[9] to react like actin, myosin and tubulin. The actual involvement in meiosis of these and many other immunologically indicated proteins is still controversial.[9] It should be noted that the above-mentioned restricted Brownian motion of chromosome regions has been shown to be inhibited only by the microtubule-depolymerizing agent nocodazole[7] and not by sodium azide, which is known to stop ATPase-driven processes.

In recent years, new groups of proteins have been isolated and shown to participate in chromosome contraction (the SMC family of proteins),[10] sister chromatid cohesion apparatus (cohesin complex) and sister chromatid separation (separins that destroy cohesion).[11]

In the folding of the chromosomes, different levels can be distinguished. Remarkably, there is a better understanding of how the DNA is organized in the chromosomes at the molecular level than at the gross chromosome level. This discrepancy may partly be due to the fact that chromosomes are too small for detailed studies at the LM level and too bulky for EM, that is, with conventional EM methods.

At the molecular level, an outstanding achievement was to reveal the association of DNA with histones to form particles called nucleosomes. The DNA molecule, the double helix itself, is 2.2 nm in diameter and makes a full helical turn of 3.4 nm (along the spiral axis) for each length of 10 nucleotide pairs of the double helix (10.6 pairs for free DNA and 10.2 pairs for nucleosomal DNA).[12] Almost two (1.75) full rounds of DNA totaling 2×83 nucleotide pairs are wound round the periphery of the nucleosome, which is roughly a cylinder 11 nm in diameter and 5.6 nm thick. It contains an octomer histone core, 6.6 nm in diameter and 5.6 nm thick, composed of two copies of each of the four histones H2A, H2B, H3 and H4. From the nucleosomes, now studied in crystallography down to a resolution of 2.8 Å,[12] polypeptide chains of the histones stick out. This is considered to play an important part in the regulation of the DNA–histone core assemblies (assembly vs disassembly), chiefly by acetylation and deacetylation of the histone tails. The DNA and histone cores are linked into a polynucleosome: an 11-nm thick 'beads-on-a-string' fiber. 'Linker DNA' of various length, from 0 to 80 nucleotide pairs, connects the nucleosomes. In this 'beads-on-a-string' association the DNA is packed lengthwise in a proportion of 6 : 1.

Chromatin, i.e. chromosome fibers, is biochemically a poorly defined entity varying with isolation sources and conditions and is composed of DNA with histones and chromosomal nonhistone proteins. The beaded-string organization is observed when chromatin is isolated and treated in buffers (pH 7.4) at low, i.e. hypotonic, salt concentration (10 mM), depleted of the divalent cations Mg^{2+} and Ca^{2+}.[13] The required deficiency of divalent cations in the isolation procedures indicates that the rather loose beaded-string configuration cannot persist under physiological conditions. However, it is not known whether living cells are capable of regulating the concentration of the divalent cations intranuclearly.

In the presence of divalent cations, 1–5 mM Mg^{2+} or/and Ca^{2+}, in neutral buffers, the isolated chromatin fibers observed have a diameter in the range 20–50 nm, depending on the isolation conditions.[13] The size is in better agreement with that of the chromatin and chromosome fibers observed in isolated whole mounts of, e.g. metaphase chromosomes.[13]

The prevalent concept of the folding of the DNA into the 30-nm chromatin fiber structure is likewise attributed only to histones. In this configuration the 11-nm polynucleosomal DNA fiber is anticipated to fold into a 30-nm solenoid with the incorporation of a molecule of histone H1 to each nucleosome. The binding site of H1 at the nucleosome has been defined but the arrangement of H1 in the 30-nm fiber organization is unclear. Recent data have positioned the globular domain of H1 close to the dyad axis, in a polar arrangement of H1 molecules along the nucleosome fiber that may influence gene regulation in addition to its structural role.[14]

The perplexity confronted in understanding the 30-nm chromatin or chromosome fiber structure is evident from various studies.[15] The observations have resulted in numerous models that can be roughly classified as (1) the original solenoid model, (2) some kind of a helical coil of the nucleosome fiber, (3) a beaded (superbead, supranucleosome, nucleomer) arrangement of the nucleosome subunits[16] and (4) a continuously variable zigzag nucleosomal ribbon.[4] The irregular zigzag nucleosomal ribbon has support from electron tomography studies,[4] cryo-electron tomography[17] and recently radiation experiments on chromatin in studies on living cells,[18] affirming linker lengths of 40 nucleotide pairs for an idealized zigzag model.

Estimating that 6–7 nucleosomes of the polynucleosomal string condense into one turn of a 30-nm thick chromatin fiber, the length of DNA is reduced in the proportion of 40 : 1. To obtain the 10^4 : 1 packing in metaphase chromosomes, further packing of 250 : 1 is required.

The prevalent opinion about packing the 30 nm chromosome fiber further into metaphase chromosomes holds that the fiber folds are packed into loops that are fixed to a chromosome scaffold structure composed of nonhistone proteins.[19] Topoisomerase II has been shown to be a main component of the scaffold proteins, making its contribution decisively important in sorting out tangling DNA strands after replication, in the condensing of chromatin loops and in the separation of the daughter chromosomes at mitosis. In addition, as mentioned above, certain new scaffold proteins have been shown to be involved in the condensation of chromosomes and in the separation of sister chromatids in mitosis.[20]

The chromosome scaffold was originally revealed in preparations of isolated metaphase chromosomes treated with high salt buffers (2 M NaCl solution) or dextran sulfate–heparin, to extract the histones and other soluble proteins. The extracted chromosomes were spread on a hypophase of a hypotonic solution. In these preparations clouds of looped dehistonized DNA could be observed surrounding a residual chromosome that principally persisted in the shape of the original metaphase chromosome. Only a residual chromosome scaffold remained after DNase digestion. With the same methods, an analogous nuclear matrix, nuclear skeleton

or cage of interphase nuclei was isolated, surrounded by clouds of looping dehistonized DNA, when digestion with nucleases was omitted.[19]

These observations suggested a looped folding of the chromatin fibers around nonhistone chromosomal scaffold proteins[19] as the principle of organizing the 30-nm chromatin fiber in chromosomes rather than a coiled-coil model. Consequently, the size, association and configuration of the regions [called scaffold-associated region (SAR) and matrix-associated region (MAR)] of looped DNA with the scaffolding proteins have been the object of various studies for the past decades, but contradictions and perplexities have hindered satisfactory concepts.[19] For example, only a slight change in the conditions for the isolation of an interphase nuclear matrix[19] resulted in a residual NE composed only of a nuclear pore complex (NPC) lamina fraction, depleted of an internal nuclear matrix. This may indicate the delicate and dynamic association of chromatin with the NE.[8,21]

It is important to recognize the apparently different organization units of the different levels of chromosome organization: (1) the polynucleosomal DNA fiber, (2) the 30-nm chromatin fiber and (3) looping of the chromatin fiber somehow around the chromosome scaffold, forming the metaphase chromosome. In interphase nuclei, chromatin is organized around analogous structures, variously termed the nuclear matrix, scaffold or skeleton, which seem to be dynamically integrated with the NPC lamina of the NE.[19,21,22]

Although the principal organization of the repeated building blocks at each organization level must be uniform, the variations and complexity in these repeats seem to increase from level to level. At the 'beads-on-a-string' level, the unit is the nucleosome with the linking DNA. For the 30-nm chromatin fiber the unit is 6–7 nucleosomes forming one turn, as assumed in the solenoid model, or their arrangement is more variable and flexible, namely an irregular nucleosomal ribbon according to the zigzag model or, as assumed in the supranucleosomal chromatin model, 7–42 nucleosomes are packed into various-sized 30–65-nm supranucleosomal units.[23] At the next higher organization level the units are the loops bound by the scaffolding structures. The loop with an associated scaffold element seems to be the elementary building block towards higher chromosome organization. Variations of the loop sizes and the clustering of the loops into, e.g. rosette-like configurations have been observed and suggested in different instances.[21,22]

How, then, do we understand the organization of the chromomeres,[13,21,22] as described in the classical studies with LM? Chromomeres are best observed in prophase chromosomes of meiosis and they must in some way be folded by the 30-nm chromatin-loop organization with scaffold proteins.

Also, the bands seen in the giant polytene chromosomes of salivary glands in, e.g. *Drosophila* must in some way fit in, i.e. be a natural consequence of the folding of the 30-nm chromatin fiber. As polytene chromosomes represent tight lateral alignments of bundles of interphase chromosomes (up to 1024 chromosomes in *Drosophila*), the bands distinguished are considered to be apposed chromomeres[13] of interphase chromosomes. Thus chromomeres seem to be organizational entities also in the interphase and not only consequences of early prophase chromosome condensation. This indicates that the folding of the 30-nm chromatin loops is actually preserved in interphase chromosomes, if we assume that polytene chromosomes are not distinctive exceptions. In addition, the size difference of the bands in polytene chromosomes must also be a natural consequence of an adequate chromosome model.[21,22]

Chromosome coiling, i.e. the coiling of the cromonemata[13] in classical descriptions from early LM studies,[24] is another example of large-scale structural chromosome features that must fit with any presumed looping of the 30-nm chromatin with scaffolding proteins, if the model concerned is to be acceptable. In animal cells, chromosome coiling is not usually distinguished after ordinary treatment, i.e. without specific procedures.[13] However, even without any specific treatments it is observed in plants with very large chromosomes (e.g. in *Tradescantia*), and also in living plant cells[24] and in unfixed animal cells processed for EM.[25]

Significantly, chromosome coiling also appears when ordinary chromosome preparations are squashed in 50%[13] or isolated with 60% acetic acid (AA),[22] indicating that chromosome preparations isolated with detergents under 'physiological' conditions or water spread[13] somehow lose or disassemble the coiling. We can also presume that the banding technique that is used today in karyotyping might have the structural background in the underlying chromosome coiling, as has been suggested.[26]

Immunological methods for staining topoisomerase II (a main scaffold protein) reveal a clearly spiralized internal core in chromosome preparations, similar to chromosome coiling.[27] Also, 3-D reconstructions by electron tomography of chromosomes, after histone extraction and DNA digestion, appear as a coiled residual chromosome structure, indicating that chromosome coiling is maintained by scaffold proteins.[28] Accordingly, in chromosome condensation, the coiling is somehow brought about in the folding of chromatin fibers by the scaffold proteins. It remains to be shown if scaffold proteins, when successfully isolated and dissolved, will self-assemble to coiled structures, especially when affiliated with DNA and histones.

Textbook diagrams and models for the higher order chromosome structure fail in giving substantial structural reasons for the several intermediate folding levels from the 30-nm chromatin fiber up to metaphase chromatids.[29] Recent discussions,[30,31] and earlier reviews of chromosome structure[22] have tried to fill this gap. Having their particular merits, most chromosome models do not meet the criteria for an adequate and unifying model – those of comprehensively accounting for different-sized chromomeres of interphase chromosomes (e.g. polytene) and meiotic prophase chromosomes, for chromosome coiling and for the origin of

Figure 1 A unified model[8,21,22] of higher-order DNA (DNA loop or chromatin fiber) folding in chromosomes: the loop-and-rosette model. The different categories of data (e.g. polytene chromosomes, Figure 2) fit best with this model. From interphase to metaphase chromosomes. (a) Single (histone-depleted) DNA loops and accumulations (duplications) of these in linear form, i.e. total or strictly local unfolding of chromomeres in a chromatid. (b) Arrangement of various size classes and organization types of chromomeres in a partly stretched-out interphase chromatid. The folding of a continuous DNA by looping: single loops which would correspond to primary replicons; double loops, multiple loops and rosettes (around ring-like cores of scaffold elements, i.e. cyclomeres[8]) and their clustering; representing the origins for different-sized chromomeres during evolution. (c) The condensed form representing the metaphase chromosome. Ring-like structures are embedded in the chromatin. Note the similarity of appearance in a section of the premeiotic X chromosome of Acheta, (d), and in a stereo pair critical-point drying (CPD)-whole mount of a Chinese hamster ovary (CHO) metaphase chromosome (prepared as in section 2.4, Procedure: 1b) shown in (e). There is a complete analogy with a chromatid of the polytene chromosome. Only the condensation is different as no lateral apposition of chromatids occurs. Instead, a linear apposition causes chromatid coiling and linear condensation of the chromosome arms. This would be chiefly due, not to the condensation of interchromomeric DNA, but rather to the tendency of the chromomere core elements (scaffold elements, i.e. cyclomeres and their subunits) to interact and assemble. Proteins of these interactions have recently been identified as the SMC family among scaffold proteins.[10,20] This results in higher-order structures such as chromosome (chromatid) coils, in which chromomeres are arranged in analogy with nucleosomes in the models of 30 nm chromatin fiber, either as in the solenoid model[15] or as in the zigzag nucleosomal ribbon model.[4] (f) 3-D reconstruction of the chromosome shown in (e), from tilt series with 6° increments (section 4.2), with MEM (section 5.4), visualized with BOB (section 6.1), shown in stereo pairs (recorded with SNAPSHOT from Silicon Graphics Inc. (SGI) display). (g) Stereo views, with 10° increments, of the reconstructed chromosome in (f). Note that chromosome coiling is recognizable as chromosome banding and the impression of bands depends also on the viewing angle. (h) Stereo series as in (g). Details of the chromosome arms with coiling (arrowhead) and ring-like structures of cyclomere size (arrows), surrounded with looping fibers of hazy chromatin. Note that these fibers are not detected in the chromosome scaffold, Figure 8(a, e) (cf. the MEM/3-D reconstruction of chromosome scaffold Figure 8a, b, e). (Reproduced from Engelhardt.[22])

Figure 1 (*Continued*)

and interplay with the chromosome scaffold and nuclear matrix.

It is worth noting that, when the chromosome material (chromatin) coils and (therefore) compacts, the two levels of coiling, (1) the 11-nm fiber to the 30-nm fiber and (2) the extended chromonema to the compacted mitotic chromosome or chromatid, appear closely similar and suggest analogous configurations of condensation (solenoid and zigzag configuration, see the notes in the legend of chromosome model, Figure 1).

Our early investigation of chromosome structure,[8] with a unifying intent, started partly from theoretical postulates that motivated a search for adequate fixing and staining methods with ruthenium red (RR) (developed for intracellular staining, see section 3.5) for meiotic chromosomes in order to reveal details in the attachment of DNA to the NE and to the SC. The methods[8] revealed the distinct presence of ring-like cores (which we named cyclomeres) in the premeiotic X chromosome of *Acheta* and also along the lateral elements of the SC. The ring-like

(h)

Figure 1 (*Continued*)

Figure 2 The loop-and-rosette model from interphase to polytene chromosomes. (a) As Figure 1. (b) As Figure 1. (c) As (b), showing that the small DNA loops (1.2–2.2 kb) as seen in polytene chromosomes,[21,22] are bound by 6–11 nucleosomes that form superbeads (30–60 nm in diameter, cf. metaphase chromosome, Figure 7), because of the short loop lengths associated with the scaffold elements. (d) Polytenisation: lateral apposition of chromatids (only four chromatids are drawn for clarity to show the principle), demonstrating the formation of the bands of different thickness. A constriction is interpreted as tendency for primary chromomeres (single loops) to fuse from separate chromatids, rather than as point of underreplication as has been formerly suggested (references in Engelhardt[22]). (e) General view of a whole mount of a CPD polytene chromosome (prepared as the metaphase chromosome in Figure 1e). (f) Stereo pairs of details at higher magnification. Ring-like structures (thin arrows) can be seen. In some rings (encircled) granular subunits are detected. (g) Ring-like alignments of scaffold-forming subunits (circles containing thin arrows) can be visualized in the bands, and they are similar to those found in metaphase chromosomes (cf. Figure 1e–h). This indicates that polytene chromosome bands are composed of the same scaffolding ring-like structures and subunits as metaphase chromosomes and this is best shown when the gross structure of the bands is also well preserved. (Reproduced from Engelhardt.[22])

structures could be traced to derivatives originating from the NE. More specifically, the structures appeared to be virtually identical with an apparently detachable nuclear part of the bipartite NPC. Striated microfilaments lining the lateral elements of the SC were revealed. Apparently, they connect neighboring cyclomeres and may represent the NE lamina. Certain lamina proteins have indeed recently been shown by immunoelectron microscopy (IEM) after DNase digestion to be present throughout the nuclear interior.[32]

It was suggested[8] that the DNA is folded around these ring-like cores, which function as the control elements for replication and transcription. The folding of DNA around these foci emerged as the most convenient way of packing DNA in interphase and metaphase chromosomes. The DNA folding (Figure 1) was presented as the loop-and-rosette model.[22] This implied a natural reason for the different sizes of chromomeres as arising naturally from replicon duplication and from the clustering of repeated replicons to rosettes. By the same principle, a model for polytene chromosomes was presented (Figure 2).[21,22] The details and consequences have been extensively discussed[22] in relation to the NE, chromosome scaffold and the nuclear matrix, and as resulting in the evolution of the chromosome structure.

This integrative model, in retrospect, involved details that strikingly resemble present-day concepts about the central control of replication machinery of eukaryotes. This machinery, with its rosette-like control elements, appears to be uniform from yeast to higher eukaryotes,[3,33] and the proposal of eukaryotic chromomeres as replication and transcription factories, also composed of rosette-form configurations, has been presented.[31] The protein composition of the replication foci involves different dynamically associated proteins, now identified.[33] A single (170-kDa) structural protein, called foci-forming activity (FFA-1), assembles as a ring-like core of the foci that generate the loop replicons. It is a novel protein according to limited sequence data.[33] It

remains to be seen if these proteins have any relationship with our early suggestions.[8]

1.2 Electron Tomography Compared with Earlier Methods

The theoretical resolution of TEM at 100 kV is 0.003 nm, which is sufficient for visualizing atoms (the van der Waals radius of the hydrogen atom being 0.12 nm and that of carbon 0.2 nm). In practice, owing to instrumental constraints and other restrictions that are difficult to overcome,[34] the resolution for modern TEM is at best 0.1 nm, which is still of the magnitude of atomic resolution accomplished, e.g. in TEM crystallography.[35] However, in biological samples the practical resolving power is often not better than about 1–2 nm. At least partly, this is in practice because details in images are in variable degrees superimposed owing to specimen thickness.

Inspection of stereo pairs greatly improves the actual resolution of structures under study, because it eliminates the superimposition of structures. This is accomplished with a mirror stereoscope (e.g. Old Delft, with auxiliary 4.5 × magnification) viewing photographic negatives in transmitted light. This technique has been found most useful and advantageous for interpreting bulky whole-mounted chromosome preparations after, e.g. digestion and treatment procedures.[22]

However, the modern 3-D approach is the ETM, i.e. TEM tomography,[36] to replace the static 3-D viewing of stereo pairs. TEM produces images that are orthogonal projections of the 3-D object under study. Tilt series of image projections of an object from 0 to $\pm 60^{\circ}$, with e.g. a 3° increment, are recovered with a eucentric goniometer specimen holder that is usually incorporated in a modern TEM instrument. The set of projections in tomography are named Radon transforms after Radon (1917), who first presented the mathematical (back-projection) method of rebuilding the original 3-D object from its projections.[36] It was only in 1968 that such an approach was put forward for 3-D reconstruction in TEM studies of biological samples,[37–39] authored in three independent papers.[40] At present ETM allows reproducible 3-D reconstructions with a resolution of 2.5–8.5 nm.[41]

Only in recent decades has ETM become a useful tool in structural biology[36,42] because of the great increase in computer power available. Chromosome studies have played a pivotal role in the development of ETM as described in a detailed review by Woodcock,[4] who also mentions that the MEM in ETM was first used in chromatin studies.[43] One of the first successful tomographic reconstructions of a whole-mounted chromosome (spread on water surface),[44] attempting to track[45] the folding of the chromatin fiber, was performed by a filtered back-projection method with an 'exact' filter algorithm.

The reasons why ETM has not yet become a widely used tool in structural biology were discussed at a recent meeting.[46] Earlier methods have been time-consuming in the extreme. It could take weeks or months to collect the amount of data that the present digital technology provides in days or hours. In addition, as the research community engaged in developing the methods has been rather small, the number of high-impact papers showing striking and convincing results is still relatively small. All this may soon change as programs, high-performance computing and instruments become available.

With the lack of efficient methods, biology has been working in a relatively flat world in trying to understand structures and functions at the molecular level. Yet these things occur in a dynamic 3-D environment. It is with ETM that we are beginning to have a closer look at this 3-D cell environment. In particular, there is at last a solid prospect of comprehending, with ETM combined with immunological,[47] in situ hybridization and with other methods, the higher order structure of chromosomes, the intricacies of which – as presented by the mingled 3-D hierarchy, the manifold of scaffold proteins,[10,11,19] and the DNA folding enigmatically connected with all this – have so far been next to impenetrable.

2 PREPARATION STEPS FOR CHROMOSOMES

2.1 General

As previously discussed,[4] there is in fact no consensus on how to prepare chromosomes for ETM investigation. In addition, ordinary EM fixation methods for, e.g. thin section studies are insufficient for revealing details in nuclear and chromosome configuration, as recognized earlier.[8] To show details of nuclei in sectioned material, staining and preservation with, e.g. various RR methods, as mentioned above, have proved to be more revealing.[8] Viruses with known surface decoration are useful as test objects for developing fixation and preservation methods for ETM.[28] Viruses can also be used as internal standards for evaluation of the 3-D preservation and resolution.

Most ordinary preparation methods used in TEM investigations are usually also convenient for ETM: (1) sections of epoxy resin embeddings, (2) whole mounts and (3) cryo-EM samples. All have their advantages and disadvantages. However, ETM has revealed shortcomings in some common preparative methods such as negative staining of, e.g. some viruses that appear very flattened (about 50%) in 3-D reconstructions.[28]

Reconstruction from sections of epoxy resin embeddings that are commonly used in EM may not be the best method. Sections, however, may often be the only choice to select an embedded specific object for reconstruction, e.g. chromosomes from certain tissue samples, cell aggregates or cultures. According to our experience, reconstructions obtained from sections are not usually as successful as those from whole mounts. The reason might be that sections suffer from various kinds of deformation that are not easily controlled, e.g. in cutting sections with the ultramicrotome and picking them on the grids, in addition to the observed thinning, up to 50%, of sections in EM, in the collection of tilt series.[4] Also, the signal-to-noise ratio is degraded in embeddings. Noise is a general problem also in cryo-TEM when unstained specimens are embedded in vitreous ice. However, the low signal-to-noise ratio may significantly be improved by removing the epoxy resin (or other embedding medium) from sections, thus making a kind of whole-mount preparation of these sections (section 3.5).

Whole mounts of, e.g. chromosomes are preferable for achieving a high signal-to-noise ratio and to secure that the whole content of the object under investigation is carried along. This is not always the situation for ultrathin sections. Sections of large organelles such as eukaryotic chromosomes and nuclei can, however, be of advantage when specimens such as whole mounts are too thick for ordinary 100–120-kV TEM; in earlier studies it was considered that 1 MV was the only choice for chromosomes,[13] for instance. Today, with modifications of preparative methods, 100–120-kV EM has proved sufficient for whole mounts, not only for whole-mounted chromosomes, but also various parts of whole-mounted cells.[47]

2.2 Chromosome Isolation and Whole Mounts

It is sufficient to present the main principles used in chromosome isolation methods because details of the various procedures developed over the years have been published and thoroughly reviewed earlier.[48,49] This equally applies to chromosome scaffold isolation,[19] where new chromosome isolation methods have been introduced.

If a high yield of chromosomes is required, chromosomes are isolated in bulk from synchronized cell cultures[49] of established cell lines that are used in cytological laboratories, e.g. HeLa (human) and CHO cells.

The procedure is as follows. Cell cultures in logarithmic growth phase, when the confluence of cells is 50–60%, are synchronized with the addition of (2 mM) thymidine in the cultivation medium and incubated for 16–22 h (depending on the cell cycle for cell lines used). The growth medium, with thymidine, is replaced with a fresh medium including a mitotic inhibitor, e.g. (0.06–0.1 $\mu g\,mL^{-1}$) Colcemid (nocodazole or vinblastine for certain cell lines), with more (10–20%) than ordinary (5%) calf serum, or fetal calf serum, and incubated for 8–12 h. Cells in mitosis are released, naturally or aided by gentle shaking, into the growth medium, because in the cell lines to be used (e.g. HeLa, CHO) mitotic cells are rounded up and detach from the bottle surface. Mitotic cells are collected from the medium by centrifugation.

It is generally essential for a successful isolation of metaphase chromosomes with most of the chromosome isolation methods used that mitotic cells are swollen by hypotony by dispersing the pellet of mitotic cells in a hypotonic solution, e.g. 75 mM KCl, for about 10 min, at room temperature (RT) or at 37 °C. Some cells need first to be washed with the hypotony solution to make the hypotony treatment effective. The swollen cells are then collected gently by centrifugation, e.g. at 800–1000 rpm for 5–10 min. The total treatment time, including the centrifugation, must not exceed 15 min. This is important when divalent cations (Mg^{2+} and Ca^{2+} or polyamines), that are essential for chromosome stabilization, are not present (but see Mendelsohn,[49] with divalent cations present).

After the hypotony treatment, any of the various chromosome isolation procedures,[19,48,49] 'physiological' or less physiological, are convenient.

The only general requirement for isolating chromosomes and nuclei and keeping them stable, with e.g. 5–10 mM (or lower) *N*-(2-hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid) (HEPES) buffer at pH 7.4, appears to be the presence of divalent cations (1–5 mM Ca^{2+} and/or Mg^{2+}) or polycations such as spermine (0.0125 mM) and spermidine (0.05 mM).[27] Monovalent salts only tend to cause aggregation.

Mitotic cells are also suited for the microspreading methods of mitotic[50] or meiotic chromosomes,[51] either without or with hypotony treatment.

The procedure is briefly as follows. In this method the cells are spread on water, or on hypotonic salt solution for more gentle spreading (0.05–0.1 M NaCl), to control better the spreading forces at the hypophase that break the cells and release the chromosomes. The chromosomes are picked from the hypophase surface on poly-L-lysine (PL) (below) or glow-discharged[51] carbon–Formvar-coated grids, after dehydration in methanol (MeOH), lightly stained with (0.001–0.002%) uranyl acetate (UA) in MeOH (30 s), washed in MeOH and dried by CPD (section 3.1).

With this elegant method, the chromosome preparations are ready for EM, without laborious purification and isolation procedures. There is the disadvantage that cytoplasmic obscuring components may also attach on the grid preparations. It is for the investigator to choose

the chromosomes on the grids, which does not seem to be too difficult a procedure as we can see in, e.g. DuPraw's splendid pictures of spread chromosomes.[5]

From the viewpoint of early chromosome morphology, these isolation methods yield the unexpected result that chromosome coiling is indistinct after any of the 'physiological' isolation or spreading methods, especially at neutral pH. The reason for this is not clearly understood.[13] Chromosomes squashed in 50% AA[13] after standard cytological fixation in MeOH–AA (3:1) do show distinct coiling.

Chromosomes isolated in bulk in 60% AA, after hypotony treatment, surprisingly show the same chromosome coiling[22] when the loose pellet of swollen cells is washed and dispersed in 60% AA. This method works also for cells that have been fixed, and stored at −20 °C, in MeOH–AA (3:1). The pellet of chromosomes, after centrifugation (1500–5000 rpm, 10–15 min), may appear indistinct depending on the initial amount of cells used. In any case, the pellet is washed in 60% AA, two or more times, and collected by centrifugation. After washing in 60% AA the chromosomes are diluted in a small amount of 60% AA and stored at +4 or −20 °C. After this procedure, a suspension of pure chromosomes, with 10–30% prophase and interphase nuclei, is found, with insignificant amount of cytoplasmic debris, when investigated by phase-contrast microscopy. Distinct chromosome coiling is visible with phase-contrast microscopy. The chromosomes do not aggregate when pelleted by centrifugation and the pellet is easily redispersed.

Polytene chromosomes can also be isolated by this method but to release them from nuclei they have to be spread on, e.g. 60% AA.[22] The chromosomes are then picked on polystyrene-coated grids (below), dehydrated, lightly stained with UA (above) and CPD (section 3.1) or *tert*-butanol dried (section 3.2).

In the AA-isolated metaphase chromosomes, the clearly preserved coiling matches classical chromosome descriptions. Thus, the AA-isolated chromosomes seem to be tempting objects to use to study the higher order chromosome structure related to chromosome coiling.

The metaphase chromosomes are mounted on EM grids by centrifugation (1–5 min, 500–1500 *g*) of a sample (5–10 µl of diluted chromosome solution, or 2–3 µl of the loose pellet) through a cushion of 60% AA, in microchambers (Figure 3) for grids (50–200 µl).

The centrifugation for mounting chromosomes on the grid is preferred as chromosomes are better preserved in their 3-D configuration than with other more direct application methods.

With AA, Formvar or carbon–Formvar-coated grids are not suitable, as they are not resistant to AA. However, grids coated with plastic (polystyrene) films (Petri dish pieces, e.g. Nunc, Nalge Nunc Inc., dissolved to make a 0.5% solution in 1,2-dichloroethane), without or with additional carbon coating, are resistant to AA.[22] These films are stronger than Formvar films but less adhesive. To prevent the film peeling off the grids, the latter may first be treated with an adhesive solution (0.01% polystyrene in benzene).[51]

Figure 3 Grid microchambers are made of plastic hematocrit tubes (1). The plug (2) of the tube is cut off (arrow) so that the plug can be easily forced to the required depth (arrowhead), into the cut-off top part (3) of the hematocrit tube to function as the bottom for the grid. Chambers of suitable sizes are thus easily obtained, e.g. 50–200 µL. The caps of a 0.5 mL microcentrifuge (Eppendorf) tubes (4) are used as adapters for (3) fitted to 0.5 mL micro-centrifuge (Eppendorf) tubes (5) (which fit into to a larger tube for a swing-out desktop centrifuge, not shown). When a swing-out desktop centrifuge is not available, the 0.5 mL cap is positioned in a 45° angle (white arrow) in a 1.5 mL microcentrifuge (Eppendorf) tube (6) with a u-form cut (white arrowhead) for the grid microchambers (7), as a substitute in a swing-out position to have the sample evenly distributed over the grid. If high centrifugation speeds (over 1500 rpm) are used, the caps at 45° angle must be fixed (glued or melted) to be kept in place. These chambers are analogous to Miller's grid chambers,[53] but faster and easier to make.

Before mounting chromosomes on the grids, fiducial gold markers that are needed for the alignment of the images of the tilt series for ETM are applied on the grids. Ni or Au grids are preferable as in the presence of gold Cu will wither when stored. Colloidal gold markers are applied by dipping the grid, one or both sides, in a drop of, e.g. 5-, 10-, 15- or 40-nm colloidal gold solution diluted to, e.g. 1:10, with filtered double-distilled water ($FddH_2O$) (0.22 µm filter, Millipore) or with PL, e.g. 0.01–0.1 mg mL^{-1} in $FddH_2O$. Being uniformly more round and less liable to aggregate, commercial immunogold particles (e.g. expired) are more advisable than self-made particles. The grid, with adhering gold suspension, is immersed in 100% MeOH that precipitates the gold on the grid. This procedure is repeated, if

necessary, to obtain the amount of gold needed. The minimum number of gold markers is three [or four[52]], preferably 8–12 or more, for the image area and the magnification used. The same gold particles must be identified on each image in a tilt series (from 0 to ±60°, e.g. in 3° increments). The size of gold particles chosen depends on the magnification that will be used for the reconstruction. In addition, a mixture of different-sized gold particles is useful for different magnifications. With PL, the dilution of the gold suspension may be increased to a much higher degree. However, we observed the drawback that when embedded in PL the gold markers look less sharp and are difficult to distinguish, especially at high tilts.

2.3 Pretreatments: Salt Extraction and Enzyme Digestions

When the chromosomes are mounted on grids, they are ready for further procedures for EM. If salt treatments or enzyme digestions are required, they must be completed at this stage, before postfixation and staining are performed.

Note that the methods that follow are suited also for other than AA-employing chromosome isolation methods[48,49] and for microspreading methods.[50,51] The point is that the chromosomes are attached on grids for easy transfer to different solutions used.

The attachment of isolated chromosomes with centrifugation, in the isolation buffer used, is secured by treating the carbon- and film-coated grids with, e.g. PL (0.1–1 mg mL^{-1} in FddH_2O), for about 1–5 min, followed by washing in drops of FddH_2O. Also, glow discharging makes the carbon or plastic film coating hydrophilic and contributes to attaching chromosomes on the grid surface.[51] The same effect is obtained by UV radiation (10–30 min) or dipping in alcohol followed by air drying (AD).

These procedures are not necessary with AA-isolated chromosomes, as they do stick on hydrophobic polystyrene film-coated grids with carbon or not. Also, PL does not harm the attachment of AA isolated chromosomes.

To remove the grid easily from the microchambers after centrifugation, follow a simple procedure.[53] After centrifugation, add 60% AA to form a convex surface in the micro-chamber. Retrieve with curved anticapillary (and antimagnetic, for Ni grids) forceps by flipping the chamber upside down to let the grid float on the surface of the hanging drop. If the grid does not detach from the bottom by slightly rocking the microchamber, it can be released by touching with a thin needle or one arm of the thin forceps on the periphery of the grid.

Grid washings, etc. are accomplished in, e.g. a large Petri dish, with moistened filter-paper, overlaid with Parafilm. The Parafilm is preferably provided with drop-sized depressions (Figure 4).

The grids are washed in HM (10 mM HEPES, pH 7.4, 5 mM $MgCl_2$) or HC (10 mM HEPES, pH 7.4, 5 mM $CaCl_2$) buffer on the Parafilm, with several droplets (1–5 min in each) to remove the AA and to balance the pH to neutral. AA-isolated chromosomes retain their morphology when transferred to water solutions containing divalent cations at neutral pH. (For a routine, it is recommended to use double-distilled water, and filter (0.22 μm, e.g. Millipore) all solutions. Also use rubber gloves, wash if powdered.)

To isolate the chromosome scaffold, histones are extracted with, e.g. 2 M NaCl solution and digested with DNase and RNase.[21,22]

However, chromosomes isolated with 60% AA, according to our sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS/PAGE) analysis and immunoblotting, show no or negligible amounts of histones,[54] the bulk of which appears in the primary 60% AA extract.

Thus extraction with 2 M NaCl-solution apparently is not necessary to extract histones. In any case, digestion with DNase I (10 μg mL^{-1}) (Boehringer), with or without RNase A (10 μg) (Boehringer), completed in 2 M NaCl in HM buffer, shows better results when monitored with DNA-specific fluorochromes, e.g. DAPI (4′,6-diamidino-2-phenylindole) (Sigma), 0.25–0.5 μg mL^{-1}, in the digestion solution.[22,54]

Figure 4 Depressions on Parafilm are obtained as follows. Take two incubation chambers with 96 wells, one with round-bottomed wells, frames removed. After inserting Parafilm (with its cover paper, not shown) between the two chambers, press together. The 'dimples' formed will ensure that the incubation drops (about 50 μL) do not float around during washing steps, when positioned in a large petri dish with moistened filter paper (to prevent the drops from drying during incubation).

After DNase I digestion in 2 M salt–HM buffer for 1–2 h at RT, no DNA-specific fluorescence can be detected after washings in 2 M salt–HM buffer followed by washings in HM buffer, and mounted in DAPI mounting medium (MM) (90% glycerine, 0.25–0.5 $\mu g\,mL^{-1}$ DAPI, in HM or HC, with antifading substances such as 10–20 mM dithiothreitol or 2-mercaptoethanol). Many commercial antifade/bleaching embedding products are available (note that the presence of divalent cations is necessary for the stability of isolated chromosomes).

Any other enzyme digestions desired are performed similarly [cf. hyaluronidase[21,22]], sequentially or if possible simultaneously, in the buffer solutions required.

Control preparations are made in the same salt buffers but without the enzyme, denatured enzymes or with enzyme inhibitors.

For enzyme digestion of resinless thick sections of whole-mounted cells, see section 3.5.

2.4 Fixation of Chromosomes

Chromosome preparations, with or without various pretreatments, preferably are chemically postfixed with glutaraldehyde (GA), a cross-linking substance and a reliable preserver of cellular ultrastructural details. Our purpose is to maintain the chromosome coiling for 3-D reconstruction. AA is not a cross-linking fixative but preserves the higher order chromosome structure, e.g. chromosome coiling, by acting as a precipitator of chromosomal nonhistone proteins. As mentioned, there is no consensus on how to preserve chromosomes for ETM,[4] so the field is open to the development of new fixation methods for testing and refining. Cautious fixation and staining are important especially after digestion–extraction steps when the residual delicate material left might easily be lost in washing steps or the configuration might change during dehydration steps before, e.g. CPD (section 3).

We have found it advantageous to use a set of various fixation procedures as a standard protocol to test different constituents and their combinations on the 3-D structural preservation and appearance. This concerns not only methods for structural chromosome studies but also any other material such as whole-mounted cells, e.g. in developing IET[47] methods (section 7).

Fixing and preserving whole mounts is a delicate procedure, as too much contrast, i.e. electron density, must be avoided to keep specimens transparent, when conventional 100–120-kV TEM is used for collecting the tilt series. The methods used in standard thin-sectioning studies, where high contrast is rarely a problem, will not work well if not modified. Little attention has been paid to developing preparative methods for whole mounts for TEM. The quality of ETM 3-D reconstructions depends as much on the development of programming methods and the performance of TEM as on the development of specimen preparative techniques suited for ETM, just as early EM depended on the instrument but equally on developing specimen preparative techniques.

CPD and other 3-D preserving methods (section 3) are used to avoid drying artifacts after the fixation procedures. It has been reported,[55] however, in scanning electron microscopy studies, that GA shrinks cells to some 45%, despite CPD. The shrinking by GA was prevented by using tannic acid (TA), after osmium tetraoxide (OT) fixation.

We tested the TA procedure using viruses as test objects. We had previously found that viruses fixed with GA appeared slightly smaller than recorded in the literature, after drying from solidified *tert*-butanol (analogous to CPD, section 3.2) for 3-D reconstructions by ETM.[28] With TA included in the fixation procedures, the size of the viruses appeared more in accordance with the reported sizes of the viruses (unpublished work).

Upon testing the TA method on chromosomes, the chromosome fibers appeared significantly thicker (40–60 nm) than chromatin fibers without TA (35–40 nm). In addition, the chromosome fibers appeared to be composed of supranucleosome-like particles of various sizes rather than a more regular fiber that the solenoid model predicts (cf. Figures 5 and 6 with Figure 7). In addition, the organization of the chromosome scaffold fibers changed appearance with TA.[54]

In our present standard fixation protocol, TA is included with GA, OT and UA with some modification of the original method.[55] Fixation controls, to test the effect of the different substances and their combinations, are used.

Dehydration and staining with UA (0.001–0.002%) in MeOH are performed in microcentrifuge tubes (Eppendorf) (1.5-mL test tubes). Curved anticapillary (and antimagnetic, for Ni grids) forceps are advantageous in the transferring steps.

The procedures are as follows. The fixation and preserving methods, for AA-isolated chromosomes and chromosome scaffolds, are accomplished with chromosomes mounted on grids:

1. (a) No postfixation;
   (b) boiling in 50% AA, for 30–60 s,[21]
   (c) wash, 3–5×, in HM or HC buffer, if the specimens are brought to salt and enzyme treatments, section 2.3;
   (d) dehydration (30, 50, 75, 100%, 10–30 s per step) in MeOH;

Figure 5 (a) Example of a low-resolution 3-D reconstruction with weighted back-projection method (WBM) of AA-isolated (HeLa) metaphase chromosome (prepared as in section 2.4, Procedure 1(b), and dried from *tert*-butanol, section 3.2), visualized with BOB (section 6.1; Figure 1f). The WBM has been low-pass filtered to 25 nm. Chromosome fibers of 25–60 nm are seen. Streaks seen in depth direction are artifacts that appear with WBM due to the missing data and other discrepancies (e.g. alignment inexactness, when tilting parameters are not accurately determined, especially with the angle of tilt axis being manually approximated, produces whirl-like streaks, arrow, in the reconstruction). [Reproduced by permission of the Center of Scientific Computing from Engelhardt et al.[28] and also from Engelhardt and Ruokolainen.[54]] This case of ETM, scanning, alignment and WBM was processed with the programs developed in Dr U. Skoglund's laboratory, Department of Cell and Molecular Biology, Karolinska Institute, Stockholm, Sweden, in 1993. (b) Details, in stereo pair of (a), at higher magnification. Chromosome fibers (20–60 nm) appear smoothed (low-pass filtered) with no sub-details detectable.

(e) staining in (0.001–0.002%) UA in MeOH for 30 s, wash in MeOH (3×);

(f) drying, with 3-D preservation methods, e.g. CPD (section 3);

Comment: boiling in 50% AA[22] causes additional purification of chromosomes from histones and cytoplasmic fragments.

2. Rapid TA method for chromosomes, modified from:[55]

- washing in HM buffer (3–5×);
- fixing, for 2–5 min, in mixture (1 : 1) of:
  1% GA in HM buffer, pH 7.4;
  0.5% OT in 0.1 M sodium cacodylate (NC) buffer, pH 7.4;
- washing in HM buffer (3–5×, 0.5–5 min);
- 0.5% TA in 0.1 M NC/HM buffer (1 : 1), 5 min;
- washing in HM buffer (3–5×, 0.5–5 min);

(a) staining with (0.001–0.01%) UA in FddH_2O, 5–10 min;

(b) without UA in FddH_2O:

- dehydration, staining in UA in MeOH, and drying as in (a).

Figure 6 (a) Chromosome (HeLa), prepared as in Figure 5, showing 3-D reconstruction with MEM (section 5.4) of a chromosome telomere, in stereo (see above). (The original magnification of the tilt series was 48 000×, scanning pixel size 20 µm, giving the original resolution as 0.42 nm. With 6 × binning, the voxel size is 2.5 nm for the volume, i.e. the 'conservative estimate'[52] of resolution is not better than about (2–4) × 2.5 nm = 5–10 nm.) Some details (cf. Figure 5a) of chromosome fibers may be detected even at this low magnification. (b) At high resolution, the chromosome fibers appear decorated with details, but are difficult to interpret. Histones are extracted by AA but DNA is present (cf. immunoblotting analysis of histones and DNA fluorescence with DAPI in Figure 8d). [Reproduced from Engelhardt and Ruokolainen.[54]]

Controls and modifications:

3. as in 2, but without TA;
4. as in 2, but without OT;
5. as in 4, but without TA;
6. as in 3, but without UA.

3 PRESERVATION METHODS FOR THREE-DIMENSIONAL RECONSTRUCTIONS

3.1 Critical-point Drying

After fixation, the whole-mounted preparations have to be dried. AD causes artifacts, shrinkage, wrinkling and distortion that destroy the 3-D configuration. Drying artifacts are caused by disruptive effects of the surface tension of the fluid from which they are dried, e.g. water but also substances such as alcohol, used for dehydration, have a surface tension high enough to destroy delicate 3-D configurations.

The problem was recognized and solved in the early development (1950) of TEM techniques by T.F. Anderson, who introduced the CPD method.[50] CPD is conventionally used for whole-mount studies with scanning electron microscopy. CPD needs, however, an apparatus where the procedures are performed at high pressure.

CPD can be briefly described as follows.[50] After the grid samples have been gradually dehydrated in steps, e.g. in MeOH, the grids are put in a grid holder in the CPD apparatus, with some dehydration fluid, and the MeOH is completely replaced with liquid carbon dioxide (CO_2), at a high pressure (60–65 atm) in several (7–10) washing steps with liquid CO_2. CPD is completed, at an elevated pressure of about 100 atm ($P_c = 73.8$ bar), by increasing the temperature to ca. 40 °C. Keeping the temperature above the critical point temperature ($T_c = 31$ °C), the pressure is slowly decreased, regulated by a relief valve. After CPD, the specimens are ready for TEM.

However, CPD has some disadvantages such as causing thermal and pressure stresses in the specimens that may be difficult to avoid. An apparatus is needed for the procedure that may not always be available. The procedure needs liquid CO_2, preferably dried to remove

Figure 7 Chromosome (AA-isolated from HeLa cells), pretreated with TA before CPD to avoid shrinkage (section 2.4, procedure 2): (a) original tilt series at 0° tilt [reproduced from Engelhardt and Ruokolainen[54]] and (b) +60° tilt with mean diameter of the 30 nm chromatin fibers (arrow) increased to 30–60 nm with globular domains 30–60 nm in diameter. (c) Stereo pair of 3-D reconstruction with MEM (section 5.4) of the chromosome fiber [shown in (a) and (b) with an arrow]. The 30–60 globular domains of the chromosome fibers appear decorated and seem to be connected by two (2–4-nm) thin strands. [Reproduced from Engelhardt and Ruokolainen.[54]]

minute amounts of water that may be present.[56] The water present in liquid CO_2 was shown[56] to be the reason for drying artifacts such as thickening of cytoskeleton fibers in the microtrabecular lattice.[57] In addition, the CPD procedure takes time to finish.

3.2 Drying from *tert*-Butanol

When an apparatus for CPD is not available, a substitute for CPD is drying of the grid samples infused with *tert*-butanol. This method needs no expensive accessory, although such an apparatus has been constructed.[58] The procedure is much faster than CPD and is claimed to give analogous results. The method is easy to accomplish, with only a few restrictions, as ordinary grids coated with Formvar are not resistant to *tert*-butanol. However, plastic films (section 2.2) that are resistant to 60% AA used in chromosome isolation with an AA procedure are suitable for *tert*-butanol drying. In addition, grids with a pure carbon film coating are usable.

After the dehydration steps with, e.g. MeOH (and staining with UA in MeOH) of the grid samples, microcentrifuge tubes (Eppendorf) (1.5 mL) are used: one tube with a mixture of MeOH–*tert*-butanol (1 : 1), and then a series of 3–4 tubes with 100% *tert*-butanol (*tert*-butanol is liquid at temperatures above 25.5 °C). The grids are washed in each step for 10–60 s. After the last step each grid is dropped to the bottom in a separate microcentrifuge tube (Eppendorf) (1.5 mL) with about 0.5 mL of *tert*-butanol until all grids are ready. After infiltration with *tert*-butanol, the fluid is changed several times, if considered necessary, by gently pouring off the liquid, keeping the grid on the bottom. For the drying procedure a small amount of *tert*-butanol is left, letting the grid attach by capillary force to the wall of the tube, then sucking the fluid droplets left on the bottom with a pipet before closing the tube. The preparations are left for a short time in a cold place (below 25.5 °C), or briefly on ice, to let the *tert*-butanol solidify. The sample-containing tubes, with lid open, are brought to a vacuum drier (e.g. Savant Speed Vac Concentrator, with centrifugation off) to let the *tert*-butanol dry off. The grids are usually seen to drop to the bottom of the tubes when the drying is completed. The operation will not take longer than 10–30 min, depending on the amount of *tert*-butanol and the degree of vacuum used. The grids must be at RT when the preparations are lifted out from the vacuum dryer, to avoid water condensing on the specimens.

3.3 Freeze-drying

Freeze-drying (FD), like CPD, needs expensive equipment. The advantage of FD over CPD and drying from solidified *tert*-butanol is that the preparations are not dehydrated with organic substances that might be destructive, extracting membranes and denaturing proteins. Partial FD is used in the freeze-etching method, where cell preparations are coated with Pt–carbon to obtain replicas of, e.g. the cell cytoskeleton, showing sharp views of actin bundles and tubulin fibers in stereo.[59] However, replicas are not useful for ETM 3-D reconstructions as the entire preparation must be transparent and not only a surface view. When FD is adapted for ETM, the time must be extended (1–3 h) so that the drying of the specimen is completed. The specimens must be prewashed with $FddH_2O$ to remove salts that will otherwise crystallize. If samples cannot maintain their configuration without salt, a volatile salt, e.g. ammonium acetate, is used at a concentration that keeps the specimen stable. Negative staining methods, e.g. of viruses, combined with FD

look superior[60] for 3-D reconstructions, as the specimen configuration is maintained and not flattened as with AD.

In brief, the procedure to freeze the specimen for FD is analogous to cryo-TEM methods. The specimen is frozen in liquid nitrogen, with a container with cryogen (e.g. liquid ethane or propane), as an intermediate fluid that is functioning as an effective conductor, for rapid freezing of the water-embedded specimen into vitrified ice. The FD is performed by raising the temperature (to −80 °C). Drying out of the preparation at high vacuum will then be possible within a reasonable time,[60] after which the preparations are ready for ETM.

3.4 Cryo-electron Tomography

Automation programs for collecting tilt series in ETM have made it possible, for 3-D reconstructions, to use single-axis cryo-ETM to collect tilt series of frozen vitrified samples, i.e. fully hydrated specimens, which are chemically unfixed, i.e. close to native state.[40] However, with this almost ideal method for specimen preservation a computer-controlled TEM and goniometer stage with cryo-holders, cooled with liquid nitrogen and accessories for preparing vitrified cryo-samples, are needed. A disadvantage is that the signal-to-noise ratio of the images usually tends to be poor, especially of unfixed and unstained specimens embedded in the vitrified ice. The noise in images is also difficult to abolish for specimens such as chromosomes as images collected in tilt series with axial tomography cannot be improved by any averaging image processing, as is possible with single particle or icosahedral virus tomography.[36,42]

The procedure is as follows. Use isolated chromosomes mounted (section 2.2) on grids, coated with perforated carbon, or better with perforated plastic film,[61] on, e.g. 50–75-mesh Ni or Au grids with colloidal (e.g. 5, 10, or 15 nm) gold markers for collecting tilt series. The idea with perforated-film coatings is to collect images of chromosomes that are preferably spanning a hole, embedded only in vitrified ice without a support, thus reducing noise and improving image contrast. Using 50-, 75-mesh or even single-slot grids, the prospect of viewing the whole tilting range from $0 \pm 60^{\circ}$ is considerably improved. The grid–specimen is washed in HM or HC buffer (≤5 mM HEPES buffer), in several droplets, before the grid, after excess buffer has been blotted off with filter-paper, is quickly dropped in a container, inserted in liquid nitrogen containing liquid ethane or propane, or better, in a mixture of ethane and propane (3 : 1) that prevents solidification of the freeze-transferring cryogens. The grids can be stored in liquid nitrogen until examination. The grid–specimen is installed in a liquid nitrogen-cooled cryo-specimen holder that protects the specimen from atmospheric humidity before cryo-TEM.

With cryo samples, automatic collection of the tilt series is the only way to avoid melting and beam damage of the specimens, as automation will shorten the exposure 10–100-fold compared with manual methods.[40]

3.5 Section Preparations

Our 3-D reconstructions with ETM, accomplished on sections of epoxy-embedded material, are not so successful as with whole mounts. Many reasons may account for this difference. As mentioned, sections have been noticed to become up to 50% thinner,[4,36] in the collection of tilt series data. If thinning takes place gradually during the collection, the reconstruction operations will severely fail, owing to unrestrained distortions of structures. The noise is more marked especially in thick sections than for whole mounts. However, thin sections also become thicker at high tilts (twofold at 60°)[52] and images are blurred.

The advantage with the sectioning technique, however, is that most material can be embedded, sectioned and structures of interest selected that would otherwise be difficult to isolate or are too bulky to study as whole mounts.

Standard fixation methods used in EM are usually inadequate for chromosomes and nuclear structure studies.[8,22] The fixation and staining methods that we have found applicable for section studies of chromosomes and nuclei are based on using RR in different combinations with GA, OT and, in dehydration before embedding in plastic resin, with UA (stain) in MeOH.

The procedure is as follows.

1. Specimens are fixed in 1–2% GA in 0.1 M NC buffer, pH 7.0–7.4, or in Ringer solution (RS), with (a) RR (750–1500 ppm) or (b) without RR, at RT, for 1–2 h or longer, washed in the NC buffer or RS.
2. Further fixed in 1% OT in the 0.1 M NC buffer or RS (2–4 h), RT, (a) with RR (750–1500 ppm) or (b) without RR, washed in the NC buffer or RS.
3. Stained in 0.1 M NC buffer or RS, (a) with RR (750–1500 ppm) or (b) without RR, for 24 h, at +4–8 °C, washed with buffer solution, briefly in water, before gradual dehydration in MeOH, then stained in 1% UA in MeOH [overnight (o/n) to several days, at +4–8 °C], washed in MeOH, transferred to absolute ethanol, propylene oxide, and finally to propylene oxide–Durcupan ACM (1 : 1), o/n.
4. Embedded in Durcupan ACM, epoxy resin (Fluka).

Controls: without RR, and with RR in the different steps and combinations.

The penetration of RR into nuclei and chromosomes can be checked in semithick section for phase-contrast LM.

Sections are cut with an ultramicrotome and mounted on grids according to standard EM thin-sectioning techniques. The sections on the grids are stained with Reynold's lead citrate (10–30 min, in a Petri dish with solid KOH to avoid precipitation), washed with freshly boiled FddH_2O and AD before examination in TEM.

Comments: importantly, to enhance the intracellular contrast with RR, it is to be used after the OT fixation (step 3). This is because OT fixation will destroy the semipermeability of cell membranes and RR will then penetrate and stain nuclei and chromosomes. Before OT fixation the intracellular penetration of RR is almost nonexistent. However, if high contrast is required, after staining with RR (step 3), postfixation with OT is added.

To study, e.g. interphase chromosomes, whole mounts of nuclei are too thick for ordinary 100–120-kV TEM. Thin sections must be used to collect the tilt series. Section thickness is, however, limited to <0.1 μm for 100–120 kV.

If thick sections must be used to incorporate spatial details, the embedding medium can also be removed. The sections are therefore changed to a kind of whole mounts. This improves the signal-to-noise ratio and makes the thick embedded material more permeable to electrons.

The material is fixed only with GA, before embedding and sectioning, and after removing the embedding, brought stepwise to buffer solution and prepared as whole mounts (section 2.4) or then processed as in bulk embedding for sectioning, i.e. fixed, stained, embedded and sectioned using standard fixation with GA or OT, or using the RR methods for chromosomes and nuclei, as presented above.

Gold markers are introduced only on the section-free side of the grid, to ensure that they do not float off when the embedding medium is removed. It may also be advisable not to poststain the sections with, e.g. Reynold's lead citrate, that may form precipitates when the embedding medium is removed. The procedure for dissolving the embedding medium from sections is somewhat different, depending on the different embedding media used.[62,63]

Removal of resin from ordinary epoxy thin sections is carried out as follows:[62]

1. Preparation of the solution: prepare a solution of seven pellets of KOH in 100 mL of absolute ethanol (the color of the solution will be light orange–brown when ready, after 1–2 days).
2. Immerse the sections (0.25–0.5 μm or thicker), mounted on carbon–Formvar grids, in the solution for several minutes (to be time tested, depending on section thickness and epoxy resin used).
3. Wash in ethanol and MeOH, with several changes.
4. CPD (section 3).

If section material seems to be lost, PL-coated grids (section 2.2) are used to ensure better that the material will stick to the grids.

Note that the method seems to be mild enough to be used with immunological methods.[62]

In addition, for enzyme digestions a method has been introduced[32] for immunostaining, e.g. interphase chromosomes. Isolated whole cells are encapsulated in agarose microbeads for the enzyme digestion and immunostaining procedures. Thick, resinless EM sections are obtained that are excellent for ETM purposes (applications in sections 2.3 and 7).

4 DATA COLLECTION

4.1 Recording of Tilt Series

Images recorded in TEM are two-dimensional (2-D) projections of a 3-D object. Owing to the large depth of focusing in TEM, all the details are usually in focus and superimposed in thick preparations, whole mounts and sections. Chromosomes lack symmetry, the kind of which is characteristic of icosahedral viruses. Thus, for 3-D reconstructions with ETM, single-axis recording of tilt projections is accomplished that after the alignment procedure is processed with the WBM and MEM.

A conservative prediction[52] of the resolution (d) obtained with single-axis ETM is correlated with the number (theoretical) of projections (N) available (from 0 to ±90°) and the object thickness (D), and is given[4] by Equation (1):

$$d = \frac{\pi D}{N} \tag{1}$$

The actual resolution realized is, however, difficult to estimate, as the number of projections is limited by the tilting range from 0 to ±60°. This tilting range is obtainable with standard specimen holders and goniometers in TEM. Special specimen stages and holders have been available earlier[64] and recently introduced for cryo-EM, including new rectangular grids.[65] Such grids with a 'grill-like' pattern have long been available, but the new 'cryo-tilting grids' are in a way improved because of the square shape, with rectilinear rims perpendicular to the tilting axis that will free the tilting procedure from shading grid bars. The disadvantage with these new grid holders is that there is no way of rotating the grid specimen. The rotation of the specimen is most important for oblong whole-mounted structures such as

chromosomes to orient them parallel to the tilt axis to record tilt series with optimal resolution in ETM.

4.2 Manual Recording

Although manual recording of tilt series in axial ETM will in the future be replaced by automatic recording (section 4.4), there are probably few laboratories today that have access to or can afford digitally controlled TEM equipped with automation facilities. Manual collection of tilt series is, after some training, a fairly quick procedure when recorded on EM photographic film plates [actually a faster procedure than recorded manually or automatically with a slow-scan charge-coupled device (CCD) camera]. The EM plates also have the advantage that the recorded area is very much larger than that covered by a CCD camera, and owing to this advantage for film plates, more and larger structures can be collected at higher magnification. This may be important not only for the structures under investigation but also for collecting gold markers for the alignment procedure, as there may not always be enough markers available in the area that the CCD chip covers. Manually, increments of less than 3° are difficult to accomplish in practice. We have found in any case that tilt series, from 0 to ±60° with a 3° increment, are sufficient for ETM reconstruction of whole mounts, and have become a standard for us. Testing tilt series, recorded with a 2° increment, has not shown significant improvements in reconstructions. However, reconstructions with a 5° increment give significantly less satisfactory results (however cf. Figure 1f, g, h).

Manual recording of tilt series is carried out as follows:

1. Check that the TEM is under optimal conditions, especially for 100 or 120 kV, which might differ from alignment settings at 60 or 80 kV.
2. Preferably, use a rotating grid holder, to adjust that the tilt axis is oriented optimally, i.e. along the length of the chromosomes.
3. Test, at low magnification, that the tilting from 0 to ±60° is attainable and not hidden, e.g. by grid bars. It is not absolutely necessary to cover the whole tilting (lacking one or even two images will not be a disaster).
4. Importantly, test that the preparation is stable, i.e. will not drift significantly during the recording. The stabilization can be improved by slight evaporation of additional carbon on grid specimens or by keeping the specimen in the electron beam, at low magnification, for some time (e.g. 5–10 min). If nothing helps to stop the movement, choose another place on the same grid for a new object, or change for a new grid specimen. Unstable specimens will easily ruin a reconstruction by blurring the whole or a great part of a tilt series. Restoring blurred images for high resolution with image processing is difficult, laborious or impossible.
5. Choose preferably the largest objective aperture, especially for whole mounts to achieve a high transparency, and a suitable magnification. According to our experience, the highest magnification with which we can collect a tilt series without significant radiation damage is about 60 000×. The electron beam must be kept as weak as possible to avoid radiation damage to the preparation. If possible, use the 'minimum-dose focusing procedure' that is available in some microscopes. This may be very useful for sensitive samples especially at high magnification.
6. A eucentric goniometer is preferable for collecting tilt series. The eucentricity of the goniometer must be adjusted as accurately as possible to be of use in collecting the tilt series. If goniometer adjustment is completed the specimen will not move and focusing will not change significantly, at least at low magnifications, when the specimen is tilted within the medium tilting range. Adjustment of the goniometer is, however, not very reliable, especially at high magnifications and tilting, and the focusing and shifting must usually be readjusted. If focusing must be corrected and if it is important to keep the magnification for each image in a tilt series unchanged, the focusing is adjusted with the *z*-control screw of the goniometer and by shifting the specimen back to position. If focusing is adjusted in a normal way during tilting, the magnification of the images will change. However, this incident will usually not be of much significance as most ETM programs will correct the scaling, i.e. magnification of each image, in the alignment procedure (section 5.1).
7. Collect the tilt series starting from 0 to ±60°, with e.g. a 3° increment (our standard). Some instructions[52] recommend starting from one extreme tilt end and move through zero to the other tilt end, to avoid sudden jumps in data collection that may occur owing to insufficient precision of the goniometer.
8. It is advisable to adjust the exposure parameters for photographic EM plates so that the plates can be developed with a machine (e.g. Kodak, used for autoradiography films) available in most laboratories. With this procedure, a check of tilt series is rapidly accomplished, so that negatives with faults, not in focus or missing can be replaced while the specimen is still in position in the microscope.

4.3 Digitalization of Photographic Negatives

Digitalization, i.e. scanning of the tilt series, is necessary for computer processing. Scanning is a more laborious

procedure than manual collection of the tilt series data on photographic negatives. At present scanning is also largely manual. According to our knowledge, there is no scanning device available with automatic feeding of EM plates to the scanner. However, devices for 35-mm film strips and also framed slide pictures can be fed and scanned automatically but not film plates of the size used in EM (e.g. 6.5 × 9 cm).

One of the advantages with EM photographic plates, as mentioned, is the large area of the specimen that can be recorded. This may partly compensate for the tiresome scanning work, in comparison with the limited view covered with a CCD camera. In addition, there are more working prospects with film plates, as they can be scanned with the resolution needed and they allow the choice of other sectors of interest, on the large plates, for scanning and with, e.g. higher resolution.

Ordinary flat-bed scanners (e.g. Umax PowerLook 2000) that we use today have a maximum resolution of 1000 dpi (in both directions, optical and mechanical), i.e. a pixel size of 25.4 μm. Better but also much more expensive scanners are available, e.g. drum scanners, but the manual scanning is much too laborious (attaching many negatives on the drum) for the improved resolution. A high-precision flat-bed scanner (Zeiss, Scan1) is available that has a pixel size of 7.5 μm (precision 2 μm), but the price is much more than 20–30 times that of an ordinary flat-bed scanner.

At a magnification of a negative of, e.g. 50 000×, scanning with 1000 dpi, the pixel resolution in the negative will accordingly be about 0.5 nm. This pixel resolution will exceed the conservative estimate of the resolution achievable, of ca. 5–8 nm, for an object with a diameter of, e.g. 100 nm (with 3° increments), according to Equation (1). However, the actual resolution frequently experienced is better than the conservative theoretical estimate.[52] In theory, the resolution that is achieved, is sufficient for twice, or owing to the many procedures in the alignment, 3–4 times the original pixel size.[52] Thus, oversampling with a 2–4 times smaller pixel size is of advantage for achieving in practice a needed resolution. As the grain size for EM photographic plates is, after chemical development procedures, estimated to be about 5 μm, this will in any case be the limit to the resolution that can be extracted from photographic negatives with digital procedures.

Scanning of the photographic negatives is carried out as follows:

1. Before scanning, dust from the negatives is removed with a soft brush, along with gentle breathing on the negatives, which will help, when the humidity is not high enough, to remove static electricity that might be a problem in dry conditions.
2. Up to eight negatives (size 6.5 × 9 cm), with shiny side down, are positioned on a flat-bed scanner (e.g. Umax PowerLook 2000).
3. The scanning is accomplished with a semiautomatic procedure together with automatic correction of contrast, of histograms, gamma values, etc. for each negative. Manual correction will take longer and the results will not necessarily be better.
4. The area and resolution (1000 dpi, optimal) are selected for the negatives and the title number for the image (corresponding to the tilt angle) and format used (e.g. jpeg) are recorded. The program automatically collects the data of the regions, according to the mentioned settings for each negative, in sequence.

Today, even with the advantages of semiautomatic scanning procedures, the completion of the scanning of all (e.g. 41, 3° increments) plates will usually take longer than the manual collection of the tilt series with TEM.

4.4 Automatic Recording

The automatic collection of tilt series data[40] will in the future replace manual recording methods. Automation is the only manner for very sensitive specimen recordings such as cryo-EMT procedures (section 3.4), which involve embedding in vitreous ice, as the exposure to the electron beam is reduced 10–100-fold, as mentioned. Automated low-dose data collection of a tilt series uses adjacent areas for correction of changes in image shift and focus. The selected area chosen for the tilt series is recognized with the cross-correlation function process. The images are recorded using a high-performance digital camera system, i.e. a cooled slow-scan CCD camera (1024 × 1024 or 2048 × 2048 pixels).[40]

Because of the cost, most laboratories will not have access to such facilities in the near future. However, to improve the resolution in ETM reconstructions, tilt series with smaller increment values are needed, e.g. 1°. The collection of tilt series with 1° increments is for practical reasons only possible with automatic data collection in digital format. Regardless of the preparative methods used, specimens suffer less radiation damage with automatic recording. In addition, the recording of the dynamic gray-scale range and avoiding image distortions are claimed to be superior with a CCD camera, in comparison with photographic film recording. All these improvements involving automatic data collection procedures are dealt with in a recent review.[40]

5 ELECTRON TOMOGRAPHY METHODS

5.1 Alignment of Tilt Series

The tilt-series images collected must be most accurately aligned to be sufficient for ETM reconstructions, especially after manual recording and scanning procedures. Alignment of the tilt series can be accomplished without markers by using the cross-correlation function method as used in the automatic data collection process. However, before the cross-correlation or other automatic method has been better refined, the use of fiducial markers has proved to be a more accurate method for the aligning of tilt series data.[4] A semiautomatic method is available, part of the program IMOD,[66] for fiducial gold marking with the advantage that some gold tags may not need to be present in all the images. However, at first glance, the method appears more complicated than manual methods in use.

As mentioned earlier, different-sized colloidal gold particles on the grids are convenient for different magnifications. The minimum number to be marked is three (or four[52]), ideally 10–20. Corresponding gold particles must be identified on all images of the collected tilt series, and preferably evenly distributed around the object to be reconstructed. Commercial gold markers are preferred, e.g. immunogold, as they appear to be more uniformly round (U. Skoglund, Karolinska Institutet, Stockholm, Sweden, personal communication) than laboratory-made markers.[67] The spherical form is important, as the program searches the midpoint pixel of the gold as the target for coordinates registered. Nevertheless, the search parameters can be turned to a minute search area to respond to manual correction, if an automatic search does not give the appropriate exactness. If sufficient gold particles cannot be found, other naturally appearing granules, etc. are usable as alternative markers within the area, only to be tracked accurately enough. It may be useful to add that in the program we have developed, the gold particles can be situated on any side or level on the grid. They need not to be on the same plane.

Our program, JPEGANIM for SGI machines,[28] used for the procedure has been appropriately designed for convenience, using interactive graphic interfaces with menus. The images of the whole tilt series are run as a movie, so each image can be sequentially viewed, back and forth, for rapidly recognizing the same gold particles in each image. The images can be contrast-enhanced temporarily or permanently, enlarged and moved to different regions when the image size exceeds the display, and processed otherwise, e.g. with unsharp masking and other filters. All these features aid in making the search and gold marking an easy and rapid operation.

When sufficient markers have been picked up and the files saved, the next step will be to test the alignment accuracy, using SOLVE from the menu in JPEGANIM. The program uses a conjugate gradient method that gives a set of overdetermined nonlinear equations that can be solved.[28] After running, the program produces a plot with evaluation of alignment correlation, in pixels, with estimates for all images and gold markers used, as graphical scores. The refinement is accomplished, when necessary, by either removing the worst gold markers, in sequence, or trying to correct the position of poor gold markers in the images with the poorest scores and rerunning the program. A set of files is used in the next step for an evaluation, which includes corrected tilting angles, scaling, midpoints and the axial angles.

The alignment procedure will then be tested with ALIGN from the menu, e.g. on a small area with only one, or a few, gold particles. A midpoint is chosen and an area framed with the mouse, producing a sequence of pictures. The z coordinate for the midpoint is obtained by using the parallax method, i.e. marking the same point from two image tilts, the zero and an end tilting image, for the best accuracy. If the same point is difficult to mark in the endmost tilt, any other image can be used. An area is then framed for the object to be aligned, from the midpoint, and the program will produce a set of aligned images, twice the size of the frame chosen.

After running the program, the accuracy of the aligned images can be tested as a movie. The movie must run smoothly and keep the midpoint in place, to obtain an accurate reconstruction. Scaling, rotations and translation of the origin are all corrected by the program.

With the test procedure adequate, the object for reconstruction framed and aligned images saved, there is saved a file including the size of the object, in pixels, with corrected tilt angles and a filtering parameter used in the reconstruction procedure. Occasionally, if a set of aligned images show sudden jumps at certain places, the corrected tilt angles are replaced with the original angles chosen, i.e. ideal values with the increments for the tilt series. (Direct goniometer readings are more precise than computed values.) A realignment (2–3 times) procedure of aligned images may also be of help in correcting the alignment for difficult tilt series.

The aligned images can be viewed in stereo mode. Gold marking in stereo can be of great help for identification in difficult circumstances. The stereo mode is also most useful in the examination and interpretation of the original EM images as stereo movies, involving image processing, contrast and filtering procedures for comparison with the 3-D reconstructions produced with ETM.

5.2 Reconstruction Methods

The ETM reconstruction programs that are used need a set of accurately aligned images, i.e. Radon transforms. The aligned projections must be twice the area of the object region selected and, as mentioned, this is accomplished by the alignment program, to be implemented for an ETM 3-D reconstruction of the object.

A reconstruction is first produced, as a test, with the WBM, a quick procedure in SGI machines (Origin 2000, 128 R12k processors, 160 Gbyte RAM). If the reconstruction with WBM shows adequate results, the reconstruction is completed with MEM. Today we use COMPAQ AlphaServer 8400, eight EV6 processors, 12 Gbyte RAM. This is advantageous, as ETM with MEM is calculation intensive. (An earlier approximation, to compare the time taken by the programs to complete a reconstruction of a certain volume, was the following: WBM took the same time in minutes as MEM in hours. However, this match is not very valid for long, as the computers are steadily upgraded, and now the time needed for MEM processing is less than half of our earlier estimate.)

5.3 Weighted Back-projection Method

For some reasons, the programs available for ETM [e.g. IMOD (URL: http://www.soapdish.colorado.edu/imod/download.html) public domain program and SPIDER & WEB (URL: http://www.wadsworth.org/spider_doc/spider/docs/spider_license.html) by license] use WBM processing for ETM reconstructions. This may partly be due to earlier limits in computing capacity. Another reason might be that WBM[36] has a long traditional line going back to Radon (1917).

In practice, our program (Backproject) does not need very much attention by the ordinary user and the reconstruction, once the filtering parameter has been determined, is an automatic procedure. The filtering parameter may be varied for an influence on resolution, smoothness or noise level of the reconstruction. However, in optimal cases, the appearance and resolution might be improved, but real improvements in reconstruction are more affected by the original quality of the tilt series and accuracy of the aligned images.

After developing and acquainting ourselves with the MEM procedure, we are now using WBM only as a rapid scrutiny method having in fact rejected WBM as a reliable reconstruction method. It is therefore unnecessary to go into the theoretical contents of WBM, as they have been presented earlier in detail.[28,36]

5.4 Maximum Entropy Method

The MEM was first introduced in an astrophysical context for filtering telescope pictures from noise, and the method initially presented significant improvements in image quality. The introduction into 3-D reconstruction procedures in structural biology was accomplished for the first time for chromosome studies, as earlier mentioned.[43] After this initial work, relatively few investigators in ETM have shown an interest in using MEM. This must be partly due to a lack of computing power and long processing times, or to poor evaluation methods used in viewing 3-D reconstructions.

In cooperation with Juha Ruokolainen (CSC, Center for Scientific Computing, Espoo, Finland), we decided to develop a MEM version of our own that was ready in early 1995. Later we extended our MEM also to a 16-bit MEM version that uses aligned 16-bit gray-scale images.[68] We became intensely aware of the need for better 3-D quality when we recognized the relatively poor accuracy of the WBM reconstructions viewed with the high-quality stereo procedures for ETM that we had developed earlier.[28]

MEM yields uniformly better reconstructions than WBM (cf. e.g. Figure 1f, g, h with Figure 5a, b), especially for whole-mount samples of chromosomes: they appear distinct in stereo viewing of the object with the volume visualization programs BOB and FUNCS (section 6.1). In addition, the noise level in WBM-reconstructed objects, as measured by α-values, is often as high as 100 or more (of the 256 gray-scale levels) when using BOB or FUNCS. With MEM the α setting is much less, often close to zero.

Another way of comparing the quality of WBM and MEM reconstructions is to examine the shape of gold markers. With WBM the missing data wedges between 60 and 90° stretch structures along the electron beam (z-axis). According to the results, MEM corrects errors due to missing data more effectively than WBM, and the gold markers are clearly less oblong with MEM.

The disadvantage with MEM is the long calculation time needed for large volumes (e.g. $400 \times 400 \times 500$ pixels), only manageable for laboratories having access to supercomputer facilities. However, even desktop computers are today as fast as yesterday's supercomputers, so it should not be long before any laboratory will have the capacity to perform such computing. For smaller volumes (e.g. $100 \times 100 \times 100$ pixels) with an ordinary desktop computer this might already, or soon, be possible within a reasonable performance time.

A description of our MEM deconvolution is as follows.[68] Solution of the deconvolution with MEM aims to minimize the function that is composed by the square of the reconstruction error (Equation 2):

$$e^2 = \|\rho - Af\|^2 \tag{2}$$

where ρ is the images and A is the back-projection operator, and by the regularizing term. The regularizing term in MEM is the entropy of the object to be reconstructed (Equation 3):

$$E = -\sum_i \sum_j f_{ij} \ln f_{ij} \tag{3}$$

where $f_{ij} = f(x_i, y_j)$ is the object to be reconstructed. The quantity f must be positive. Combining Equations (2) and (3), the problem may now be presented as an optimizing problem: search for f_{ij} such that the expression $\mathbf{A}$ is at minimum (Equation 4):

$$\mathbf{A} = \sum_i \sum_j f_{ij} \ln f_{ij} + \lambda \|\rho - Af\|^2 \tag{4}$$

where A is the Radon transform operator representing the reconstruction function as back-projections of images. The Lagrange coefficient, λ, is a regularization parameter, which weights the reconstruction error with respect to the entropy.

As mentioned, the experiences with MEM are promising. For example, noise is notably eliminated, and so is the waving that the Fourier transformation also causes. In addition, according to the definition, MEM produces a positive reconstruction of the object, in contrast with the Fourier transformation method. The density quantity should be positive. Additional MEM deconvolution procedures can be found elsewhere[36,43] and in a recent application.[41]

Our MEM procedure (MaxEntropy) is almost as transparent for the user as WBM. In the file that is created in the saving of the aligned images, the regularization parameter is added after the filtering (default) value. If problems appear, often seen as regions of minor stripes or bands, then this regulating parameter is tested with other values until the reconstruction has been refined to remove the minor distortions.

There is an additional regularization parameter for our 16-bit MEM. This 16-bit MEM, as yet not much used, will be especially useful when 16-bit gray-scale images are accessible with high-performance 16-bit CCD cameras with automatic data collection of tilt series, especially in cryo-ETM procedures.

As already mentioned, MEM is executed on a COMPAQ AlphaServer (8400) SG 140 (eight processors, 12 Gbyte RAM), especially for large volumes. However, the data have to be converted to be usable for viewing the volumes in the SGI machines, as the bytes in the Alpha machines are in a different order. This inconsistency is corrected by using a conversion program in the Alpha machine to make the volumes applicable for SGI machines.

Actually, a set of different conversion and other subprograms are repeatedly used. There is no reason to go into all the details, as different programs and machine set-ups may require different modifications.

5.5 Dual-axis Tilting Method

In conventional single-axis tilt series, the tilts used are limited to the range from 0 to $\pm 60^\circ$. As already mentioned (section 4.1), grid holders are available for increasing the tilting range, e.g. from 0 to $\pm 70^\circ$ (or even up to 80°), but at the highest tilting ranges occultation easily occurs, and for sections the thickness will in general become too large, especially at very high tilts, e.g. two times thicker at 60° and three times thicker at 70°,[52] for collecting reliable data with conventional 100–120-kV TEM.

Methods have recently been introduced to reduce the missing data wedge, e.g. between 60 and 90°, by using dual-axis tomography tilt series,[69,70] The two programs transform the missing wedge to a missing pyramid, and combine somewhat differently the two orthogonal single-axis tilt series obtained by 90° rotation.

The dual-axis tilting approach has shown improvements in some situations, e.g. membrane vesicles appear restored from distortions in comparison with the single-axis method. Detailed instructions on the procedure, with or without a specimen-rotating grid holder, have recently been prescribed.[52]

It seems doubtful if any improvements can be obtained for oblong structures such as chromosomes and chromatin fibers, as microtubules oriented perpendicular to the tilt axis fade and are lost in reconstructions.[52] In any case, improvements have been claimed, at least in some cases, also for microtubules.[70] According to our experience, long structures, e.g. microvilli, when tilted perpendicular to the tilt axis, appear very unsharp and faded along the reconstruction. It is obvious that the dual-tilting axis method is useful only for fairly rounded objects that need not be specially oriented for collecting tilt series.

In our experience, to test cryo-preserved preparations (in cooperation with H. Cheng, Karolinska Institute, Stockholm, Sweden, and M. Marko, Wadsworth Center, Albany, NY, USA) using our MEM procedure and combining the dual-axis tilt reconstructions with IMOD,[70] no clearly distinct improvements emerged. However, all possible refinements have not yet been accomplished and the original tilt series from the sections used were, for some unknown reasons, difficult to align accurately. Such inaccuracies may have contributed to the unsatisfactory result, as the improvements usually detected with a dual-axis tilting method seem to be the most delicate[70] and advantageous when all basic parameters are refined to the optimum.

6 RENDERING OF RECONSTRUCTED CHROMOSOMES

6.1 Visualization of Three-dimensional Reconstructions

When a chromosome reconstruction has been completed with WBM or MEM, there are several ways to visualize 3-D volumes. In any case the reconstruction must be in the right format for the program. For such conversions another set of programs are used.

As indicated, we regularly use two programs for SGI machines, BOB (a public domain program, University of Minnesota, Graphic Visualization Laboratory, Army High Performance Computing Research Center) and FUNCS,[28] that efficiently display volumes of 3-D reconstructions of, e.g., chromosomes in stereo mode.

The SGI workstations (Octane, 1 Gbyte RAM, and Onyx2, 4 Gbyte RAM with 4 MIPS R10000 processors and InfiniteReality2E-graphics), with high-frequency displays, and provided with liquid-crystal stereo (Crystal Eyes) eyeglasses, synchronized by an infrared light device controlled by the computer, show images in color stereo mode. According to our experience, stereo viewing is the only way of even beginning to comprehend the geometry and 3-D structure of chromosomes (Figures 1f, g, h, 8a, c, 9a, b and 10b, c). Other methods might involve

Figure 8 (a) Chromosome scaffold, stereo pair of 3-D reconstruction with MEM, section 5.4. [AA-isolated chromosomes from HeLa cells, prepared as in section 2.4, procedure: 1(b) and (c), then treated as in section 2.3, with DNase and RNase digestion; then as in section 2.4, Procedure 1(d) and dried from *tert*-butanol, section 3.2.] Typical coiling appears in chromosomes, although they are depleted of histones and DNA, showing that scaffold elements are maintaining the coiling. The pattern and structures that can be detected are wholly in agreement with the unified loop-and-rosette chromosome model (Figure 1). The unified model gives predictions about the structure of the chromosome core regions, i.e. scaffold, in all details. Ring-like structures that are in agreement with the size of cyclomeres are detected (arrows) in the chromosome scaffold. In addition, gyres of the scaffold macrocoils measure to fit two rows of cyclomeres, e.g. in a zigzag pattern [cf. zigzag ribbon model for arranging nucleosomes in the 30 nm chromosome fiber[4,17]], although minor coils,[25] e.g. solenoid arrangement of cyclomeres, can also be seen closer to the centromere region, indicating that the structure of the chromosome coiling is versatile. (b) Hard copy, i.e. solid 3-D plastic model (section 9) produced earlier[28] from a WBM 3-D reconstruction. Coiling and many of the ring-like structures are found in the hard copy and importantly arch-like bends (arrow) that the unified loop-and-rosette model also predicts (cf. Figures 1b and 2c). (c) Immunoblottings with antibody (Ab) to H1 and H2b (antibodies to histones H1 and H2b kindly provided by Dr M. Bustin, NIH, Bethesda, MD, and Dr B.D. Stollar, Department of Biochemistry, Tufts University School of Medicine, Boston, MA, USA, respectively): 60% AA-isolated chromosome pellet, 60% AA-isolated chromosome pellet that has been further boiled (0.5–2 min) in 50% AA, and as positive controls the supernatant of 60% AA extract and of whole cells. LMW (low molecular weight) protein markers (Bio-Rad). Text in each sample column. (d) AA-isolated chromosomes fluoresce brightly with the DNA-specific fluorochrome DAPI. Digestion with nucleases DNase I and RNase A (section 2.3) remove all detectable fluorescence, but chromosome scaffolds retain their original shape and can be seen in LM (text in each picture). [(a–d) partly published in Engelhardt et al.[28,54]] (e) Stereo series of the chromosome scaffold arm [see (a)] with 10° increments around the tilting axis for each row, to observe the chromosome coiling from various directions. Ring-like structures of cyclomere size (arrows) are present. Thicker gyres (arrowheads) of the scaffolding coils seem to be fitted with two rows of cyclomeres in a zigzag pattern as suggested in the unified loop-and-rosette chromosome model [Figure 1, and cf. (a)]. [There is resemblance to intact chromosomes, with histones and DNA, having 'large-scale domains, roughly 100–130 nm in width', as described in EM tomographic sections of metaphase and telophase chromosomes by Belmont;[30] cf. his Figure 1.]

Figure 8 (*Continued*)

underestimation of the structural complexity and be rather pointless in really getting to grips with the 3-D reconstruction by ETM.

The 3-D reconstructions of chromosome are shown as translucent objects, regulated by alpha blending, and color may be introduced for different gray-scale ranges, composed of voxels, the size and density correlating with the pixel resolution of the original EM image projections. Viewed in mono and gray-scale, the reconstructed 3-D chromosomes look identical with the original 2-D EM images. Gray-scale viewing in stereo mode may actually be a more correct way to resolve complicated structures than replacing gray-scale values with various colors; although the colors look inspiring, they may actually confuse, not only beginners, rather than clear up complex structures. However, replacing gray-scale values with different colors can effectively intensify minute density differences for detection and analysis (e.g. Figure 9b).

(a)

(b)

Figure 9 (a) Stereo pair of MEM 3-D reconstructed chromosome scaffold of a small (HeLa) chromosome (prepared as in Figure 8a) visualized with BOB (section 6.1; cf. Figure 1f). Coiling is obviously not prevalent in this size class of chromosomes, as it would require a certain length. However, scaffold fibers can be studied in more detail. Scaffold fibers appear as disordered fibers and arches or have an open ring-like form (arrow), as the loop-and-rosette model predicts. In the background fiducial gold markers (red color) are seen. [Reproduced from Engelhardt and Ruokolainen[54]]. (b) Detail from (a) (thick arrowhead), stereo series of scaffold fibers rotated along the tilting axis, with 10° increments. Along the fiber perforation-like structures are obvious (light blue). A 10-nm gold particle (red) is visible among the fibers. A description of the perforation pattern of the fiber structure has been presented earlier[54] as peripherally located toroid-like structures of about 8 nm in outer diameter with a central hole of about 4 nm, but also open toroids could be detected along the spirally wound scaffold fibers. It was suggested that the perforations (toroids) are manifestations of topoisomerase II (a main scaffold protein). [Stereo pair in (b) reproduced from Engelhardt and Ruokolainen.[54]]

Furthermore, a 3-D reconstruction can be rotated and moved in any direction, enlarged, sliced and details can be cut out for closer viewing, or joining of voxels can smoothly display large volumes.

We use the programs for different aims. BOB is an easy and fast way for regular viewing of large and small volumes in stereo mode. FUNCS is slightly more difficult to use, but includes more features, such as introducing different-colored lights from different directions, interpolation of volumes or showing the volume as surface view (isosurfaces). Most importantly, FUNCS allows high-quality animations (section 6.2).

Other methods, such as sectioning the volume from any direction into 2-D slices that can be viewed in series, as a slow or rapid movie, also in stereo mode, or from all directions simultaneously, are available for dissecting and analyzing reconstructions.[52] These and other features are found in such programs as IMOD and SPIDER & WEB (section 5.3).

6.2 Producing Stereo Animations from Three-dimensional Volumes

The problem, when viewing high-resolution reconstructions of, e.g. chromosomes, is that volumes (over 200 × 200 × 200 pixels) become slow, i.e. scenarios have to be recalculated by the computer, e.g. when the image is enlarged or the direction is slightly changed, e.g. in tracking structures in detail. The recalculation takes time, relative to the size of volume, which causes difficulties in following details when minor structural changes take place, i.e. causes loss of the track.

New effective high-end SGI workstations (as detailed in section 6.1) are available that may solve the calculation problems at least up to some volume sizes. However, the programs have to be updated (rewritten) for new workstations.

A much simpler and effective way to solve this kind of problem, which we have used earlier, is by creating high-resolution animations[28] around an axis, usually the tilting axis (Figures 1g, h, 8e, 9b, 10c). These animations can be produced from any size of reconstructions that are recovered with ETM, including interpolations and illumination from different directions, both of which improve significantly the appearance of details. Animations are produced with FUNCS, around the tilt axis with, e.g. 10° increments and three-time interpolations. However, animations with smaller increments, e.g. 1–5°, improve the tracking of details considerably. Depending on the size of the volume, the animations are produced in less than 1 h up to o/n.

Figure 10 (a) Tilt picture (+45°) from the tilt series (0 to ±60°, in 3° increments) of chromosome scaffold (prepared as in Figure 8a). Overhanging scaffold fibers are seen originating from the chromosome scaffold torn from the carbon–Formvar film, visible at the picture base with 10-nm gold particles. The freely dangling scaffold fibers were used for the 3-D reconstruction to achieve the highest resolution. After high-resolution scanning the pixel size corresponds to 0.4 nm in the tilt series, collected at 58 000× magnification. [Another tilt picture from this series published in Engelhardt and Ruokolainen.[54]] (b) Stereo pair of MEM 3-D reconstruction of freely hanging scaffold fibers. Fiducial 10-nm gold particles are seen tagged to the fibers. (c) Stereo series, with 10° increment, of MEM 3-D reconstruction of top part [arrowhead in (a) and (b)] of the scaffold fibers, from high-resolution animation series (interpolating pixel vs voxel size to 0.1 nm). In stereo, an impression is made of a slender mostly peripheral lace-like structure, demarcating sharply the scaffold fiber periphery. [Outer mesh diameter 3.5 nm, inner mesh diameter and thickness about 1.5 nm. These values are rough as they are on or below the limit of the 'conservative estimate of resolution',[52] which is about 3 nm, Equation 1.] Stereo viewing reveals that the gold particles are inside the stretched fibers. This confirms that the fibers are very empty indeed. If the lace-like covering is real it could be part or derivative of the NE lamina that has recently been shown to be found inside the nuclei with IEM[32] after DNase digestion. [Stereo pair of this series published in Engelhardt and Ruokolainen.[54]]

(c)

Figure 10 (*Continued*)

The images of an animation are saved in high-quality jpeg format and viewed with JPEGANIM, in stereo mode. Also, as already mentioned, from the menu of JPEGANIM, the movies can be magnified, moved to different regions, and structures can be measured with great precision, run with different speeds or very accurately by stepwise moving, smoothly, frame after frame. With these animations, the stereo viewing is not disturbed by blurring recalculations as the animations are sequences of ready-processed images that are all in the memory of the SGI workstation (as detailed in section 6.2).

6.3 Computer-aided Virtual Environment

Another means of 3-D visualization of volumes that we have recently used for viewing 3-D reconstructions of chromosomes, usable also for an audience, is the computer-aided virtual environment (CAVE) (available, e.g. at the Helsinki University of Technology).

The CAVE is a room, with wall-sized displays (three walls and the floor), controlled by a high-end SGI workstation (Onyx2, Infinitereality, 1 Gbyte RAM and four R10000 processors). High-end precision projectors, controlled by the SGI workstation, project the images of the volume on the walls. The viewers stand in the middle of the CAVE with liquid-crystal stereo (Crystal Eyes) eyeglasses. The rotating volume can be seen in 3-D form from all directions and from within at high resolution.

No doubt the 3-D view obtained is most impressive with very accurate details, as the whole volume is seen with all details and not limited by frames, as happens with

ordinary computer displays, when the object is magnified. The impression is that this is not only an excellent method for showing 3-D reconstructions for a group, to promote meaningful discussions among researchers, but also an important tool for perceiving structures that cannot be easily displayed in other ways.

7 IMMUNOELECTRON TOMOGRAPHY

The ultimate goal, in structural studies and particularly in 3-D reconstruction studies with ETM of biological specimens, would be to recognize different proteins, nucleic acids and other macromolecular assemblies straight from their structural 3-D configuration.

Before this ideal goal, achievable perhaps in the distant future, we have to use some other means of identification, such as immunological methods. Immunological methods work strikingly adequately in locating specific proteins at LM and EM levels.[67]

We have recently developed IET methods.[47] In principle, these methods do not differ much from ordinary IEM methods. We have used whole-mounted cells grown on EM grids for IET. Primarily, whole-mounted cells are not usually used in IEM in the way that thin sectioning or whole mounts of protein assemblies or objects of comparable size have been used. In whole-mounted cells or objects such as chromosomes, the immunolabeling would be difficult to distinguish because of the thickness and superimposition of immunolabeling in the 2-D images in TEM of such samples.

However, whole mounts are very suitable for IET. Instead of attaching gold markers on the grids for aligning the tilt series, immunogold labeling will be most adequate for the alignment. The different-sized immunogold markers will identify different proteins on the same preparations.

The problems in the development procedures were obtaining clean control preparations and preserving the cell ultrastructure, antigenic properties of the proteins and making cells permeable to immunogold labeling. In our IET reconstructions, we could easily see 5- and 10-nm gold conjugates. In addition, in distinct reconstructions, 1.4-nm immunogold (Nanoprobes Inc.) was detected especially clearly in overhanging microvilli, where the carbon–Formvar support had been torn away. This was to accomplish a set of high-resolution tilt series, so that the resolution was not obstructed by the support (Figure 11).

It remains to be seen how IET works for whole-mounted chromosomes, but we see no prominent difficulties. The steric hindrance by DNA present may cause penetration problems for immunogolds used. Thus, DNase-treated chromosomes, i.e. isolated chromosome scaffolds, would be the primary target in identifying scaffold proteins in 3-D reconstructions. The antigenicity of proteins may be hampered by 60% AA isolation of chromosomes, so that a more physiological method for chromosome scaffold isolation[19] might be immunologically more suitable. In any case, 60% AA-extracted histones had not lost their antigenic properties (Figure 8c) as shown in immunoblottings.[54]

IET procedures[47] modified for whole-mounted chromosomes are as follows. The starting material is chromosomes or chromosome scaffolds[19] mounted on PL-coated or glow-discharged carbon–Formvar–Ni grids[51] (section 2.2). The treatments are performed on Parafilms, with drop-sized depressions on wet filter-paper in Petri dishes (section 2.3). Washings and incubations are performed at RT, preferably on a tabletop shaker (gentle shaking). All solutions are filtered through a 0.22 μm (Millipore) filter. Small amounts that are difficult to filter are centrifuged, e.g. Ab mixtures, GA and OT solutions.

1. Prefixing in 0.125% GA in HM solution, 15 min.
2. Without prefixing:

   Wash in HM solution, several drops.

   Preincubation: wash and incubate o/n in TXHS (0.05% Triton X-100, 30 mM HEPES, pH 7.4, 0.1–0.5 M NaCl, 20 mM KCl, 5 mM $MgCl_2$, 20 mM glycine, 0.02% NaN_3), with (a) 0.5% fish gelatin (FG), or (b) no FG, 1–2 h at RT, and/or +4 °C o/n.

   (a) Incubation in primary Ab mixture (1 + 2):

      (i) Rabbit polyclonal Ab for protein 1 (LM-checked, e.g. $1:50–1:10^3$).

      (ii) Mouse monoclonal Ab for protein 2 (LM-checked, e.g. 1:25).

      Diluted in (a) TXHS + FG or (b) TXHS, 1–2 h at RT, and +4 °C o/n.

      Wash in TXHS, in several drops (1–10 min per drop).

   (b) Incubation in secondary gold-conjugated Ab mixtures; examples:

      (i) Mixture: goat anti-rabbit (GAR)–10 nm gold (1:25 dilution, Sigma) with GAR–1.4 nm gold (1:25 dilution, fluoronanogold, Nanoprobes Inc.) and goat anti-mouse (GAM)–5 nm gold (1:25 dilution, Sigma), diluted in (a) TXHS + FG or (b) TXHS, and/or

Figure 11 Examples of IET. Microvillar proteins in MRC-7 cells. Overhanging microvilli (without carbon–Formvar support) of MCF-7 cells,[47] will be representative samples of IET methods developed that may analogously be used for IET chromosome studies (section 7). (a) Stereo pair (BOB, cf. Figure 1f) of microvillar ezrin labeled with 10-nm gold particles. The specimen was postfixed with the GA, OT, TA method[47] (section 7). TA was used to minimize shrinkage of the samples after GA fixation (sections 2.4 and 7). The raw IET data (sections 4.2, 4.3 and 5.1) were processed with MEM (section 5.4). The 3-D preservation using TA shows more substructural details than without TA [cf. (d)]. (b) A stereo pair image [as in (a)] of microvillar ezrin and mucin. The specimen was postfixed with the TA method [as in (a)]. Ezrin was labeled with 10- and 1.4-nm gold conjugates and mucin with 5-nm gold conjugates. MEM 3-D reconstruction methods were used [cf. (a)]. Ezrin labeled with 1.4-nm gold particles is marked by arrows. Arrow with ribbon shows clusters of 1.4-nm gold particles. The intermediate-sized particles depict mucin labeled with 5-nm gold conjugates. (b1) Detail of (b) showing a stereo pair of 1.4-nm gold clusters (arrow) at higher magnification. (b2) Details in a single 10-nm gold particle. (c) IET reconstructed with WBM (section 5.3), for comparison of the same microvilli as in (b) with MEM procedure. Gold labels are seen but the 3-D reconstruction is less sharp and more noisy. (d) Stereo pair image [as in (a)] of MEM 3-D reconstructed microvillus as a control without TA (section 7). Ezrin was labeled with 10- and 1.4-nm gold conjugates and mucin with 5-nm gold conjugates. The 1.4-nm gold conjugates are present but more difficult to detect than in (b) with TA (presumably the detection of 1.4-nm particle size is more difficult owing to the shrinkage caused by GA fixation and CPD, which the treatment with TA seems to prevent.[55] [Reproduced from Engelhardt et al.[47]]

Figure 11 (*Continued*)

(ii) Mixture: GAR–10 nm gold (1 : 25 dilution) with GAM–5 nm gold (1 : 25 dilution) and GAM–1.4 nm gold (1 : 25 dilution), in (a) TXHS + FG or (b) TXHS.

Incubation: 1–2 h at RT and 4 °C o/n.

Wash in TXHS, several drops (1–10 min per drop).

Wash in HM, several drops.

3. Postfixing: 1.25% GA (1 h–o/n) in HM, (a) add OT (from e.g. 1% stock solution) in 0.1 M NC buffer, pH 7.4, to 0.3% OT as a mixture with GA in HM, 1–5 min, RT; (b) no OT.

   Wash in HM, several drops.

4. TA: (a) 1% TA in 0.1 M NC and HM (1 : 1), 5 min (for whole-mounted cells 1 h–o/n); (b) no TA.

   Wash in HM, several drops.

5. Dehydrated in 30, 50, 75, 100% MeOH.
6. Stain in 0.001–0.002% UA in MeOH (30 s), wash in MeOH.
7. CPD or other 3-D-preserving drying methods (section 3).

Controls: In IET controls, control (preimmune) serum was used or primary serum Abs were omitted and samples were postfixed only in GA (with or without TA), with no UA before step 7.

LM: immunofluorescence fixed in 3.5% paraformaldehyde in HM, using secondary GAR–fluorescein isothiocyanate (FITC) and/or GAM–Rhodamine, according to standard protocols,[51] mounted in DAPI/MM.

For immunolabeling of resinless thick sections, enzyme-digested or not, of whole-mounted cells, see section 3.5.

8 IN SITU HYBRIDIZATION ELECTRON TOMOGRAPHY

Analogous with IET methods, the same development concerns in situ hybridization electron tomography studies. In situ hybridization methods have been accomplished for EM earlier[67] and in microspreading of meiotic chromosomes, i.e. EMISH (electron microscopy in situ hybridization).[51] In principle the very same methods would be sufficient.

In addition, LM in situ hybridization techniques are standard procedures[51] only to replace, e.g. after the first biotin–avidin amplification procedures, the second one with gold-conjugated avidin, and replacing AD with, e.g. CPD (section 3).

FISH (fluorescence in situ hybridization) preparations are frequently contaminated with background signals that may be difficult to eliminate and spoil the accuracy required with in situ hybridization for EM preparations. In addition, cytoplasmic fragments regularly contaminate LM and microspreading preparations in EM studies.

It is therefore essential to strive for chromosome purification methods where cytoplasmic contaminations are eliminated, to be useful for in situ ETM. In addition, it is important to refine blocking methods to remove any background and unspecific labeling.

Superimposing contaminants and background labeling may disturb ordinary in situ hybridization EM preparations. ETM has the advantage that from the 3-D reconstructions, superimposed contaminating materials may be eliminated, as chromosomes with specific labeling can be cut out from surrounding material with ETM procedures and the pure 3-D chromosome reconstructions can be analyzed separately in detail.

9 HARD COPIES, PRODUCTION OF SOLID THREE-DIMENSIONAL MODELS

Hard copies, e.g. photographic prints, are produced of computer images, and hard copies of 3-D reconstructions of, e.g. chromosomes can also be produced, as we showed years ago.[28] This manufacturing procedure is called rapid prototyping technology (RPT). Today also the term laser stereolithography (laser photo-polymer technology) is used, including various other manufacturing procedures.

The solid 3-D model produced by the RPT method of our reconstructed chromosome scaffold is presented with all details. Our primary 3-D reproduction had to be supported by solid bars to maintain the spatial relationship of various parts. The material, from which the model is manufactured is nontransparent and somewhat fragile. The height is 13 cm and the width and thickness are relative to the computer reconstruction. Also, most of the details, although complicated, are reproduced with comparative accuracy that is limited only by the nontransparent material that is less useful for structural studies.

The technology to reproduce solid 3-D models of 3-D reconstructions is advancing rapidly. This will bring us solid 3-D models of more transparent material with different colors to accentuate, e.g. internal structures with the same density, i.e. isosurfaces. Such hard copies will be a great aid for complex structural studies that chromosome structures particularly require.

We must admit, however, that although the impression of the original chromosome scaffold appeared as a typical chromosomal coil, and the impression of a coiling structure prevailed in the viewing of the 3-D reconstruction in the computer, the solid 3-D model could neither verify nor disprove the coiling configuration.

Actually, we can realize that this apparent conflict may arise because the scaffold is not a uniform structure but is composed of thicker and thinner segments, i.e. coiling does not look very regular at a closer look. Owing to the irregular thickness, the coil appears also dually as sequences of bands and interbands, although the bands are actually just thicker clusters of the coiling scaffold structure and the interbands are thinner regions of the coiling scaffold, as the loop-and-rosette model predicts.

The higher level structure of chromosomes is indeed very complex. Neither the 3-D reconstruction (performed with WBM) nor the solid 3-D model allowed unambiguous structural interpretation of configurations. Further, the problematic situation of chromosome coiling (cf. Figures 1f, g, h and 8a, e) resembles the level of the 30-nm chromatin fiber.[4,17] Chromosome structures at all levels are much more complicated than we think and the methods are not yet sufficiently developed.

10 METHOD DEVELOPMENT

A program and instruments to collect tilt series automatically for ETM are now available. An accurate automatic alignment procedure, at least as accurate as the fiducial gold markers, would also be very useful. The two programs would constitute the all-automatic ETM kit. The system would use a supercomputer facility in connection with a computer-controlled TEM. Not too many obstacles are likely to be in the way of such a development. Whenever possible, the cryo methods would be used on unfixed and unstained specimens embedded in vitrified ice. The cryo-TEM techniques are fast and specimens are relatively easy to prepare and fully hydrated, i.e. close to the native state. However, the problem of noisy images in cryo preparations must be solved with filtration programs. We recently succeeded in eliminating at least partly the noise from some cryo-embedded preparations, with programs that we developed. The noise problem in cryo-specimens may thus be tractable.

A viewing room and facility, such as CAVE or VR (virtual reality) CUBE (Royal University of Technology, Stockholm, Sweden), will be indispensable for thorough analyses of high-resolution 3-D reconstructions.

With chromosome structure as an example, we realize that many structures are too complex for comprehension with present 3-D reconstruction methods, including hardware solid 3-D models. Thorough analysis with methods and programs may be useful, e.g. for tracking specified structures manually, semiautomatically or automatically, in 3-D form, from section to section. Such tracking studies on whole-mounted chromosomes were started as early as 1988[45] with an automatic algorithm included in the program IMAGIC. Semiautomatic programs for this purpose are now available, such as STERECON[71] and TINKERBELL[72] and in the framework of IMOD.[66]

A new exciting method (SITUS) (a public domain program),[73] available for testing, combines protein data from high resolution X-ray crystallography, available from the Protein Data Bank, with 3-D reconstructions with ETM. The program, which makes use of neural nets, searches the known protein configuration, as 'fingerprints', in the volume and, if found, displays its localization and orientation. This method would yield an identification method for proteins, without immunological techniques, and reveal their structure in the ETM-created volume at atomic resolution.

ACKNOWLEDGMENTS

For acquainting me with the practice of electron tomography, in 1989, I thank Lisa Borland, Marin van Heel

and Professor E. Zeitler, Head, Fritz Haber Institute, Berlin. Initial tips on MEM and further instruction on tomography methods, from Docent Ulf Skoglund, his tomography group (Lars-Göran Öfverstedt and Hans Mehlin) and Professor B. Daneholt, Head, Department of Cell and Molecular Biology, Karolinska Institute, Stockholm, are gratefully acknowledged. The visit to Karolinska Institute in 1993 was supported by EMBO and Nordiska Ministerrådet. Financial support from the foundations Maud Kuistilan Säätiö and Oskar Öflunds Stiftelse is gratefully acknowledged. At CSC-Scientific Computing, Espoo, Finland, the professional skills of Juha Ruokolainen, in both programming efficiency and physical theories, have been indispensable. Jukka Heikkonen of the Laboratory of Computational Engineering and Jorma Laaksonen of the Laboratory of Computer and Information Science, Helsinki University of Technology, have cooperated in the development and refinement of programs. For working facilities, for advice and for comments on the manuscript I thank Professor Antti Vaheri, Head, and Professor Carl-Henrik von Bonsdorff, Haartman Institute, University of Helsinki. The manuscript was thoroughly discussed with and scrutinized by Kalevi Pusa, who made a number of useful suggestions.

ABBREVIATIONS AND ACRONYMS

AA	Acetic Acid
Ab	Antibody
AD	Air Drying
CAVE	Computer-aided Virtual Environment
CCD	Charge-coupled Device
CHO	Chinese Hamster Ovary
CPD	Critical-point Drying
DAPI	4′,6-Diamidino-2-phenylindole
EM	Electron Microscopy
EMISH	Electron Microscopy In Situ Hybridization
ETM	Electron Tomography Method
FD	Freeze-drying
$FddH_2O$	Filtered Double-distilled Water
FG	Fish Gelatin
FISH	Fluorescence In Situ Hybridization
FITC	Fluorescein Isothiocyanate
GA	Glutaraldehyde
GAM	Goat Anti-mouse
GAR	Goat Anti-rabbit
HC	10 mM HEPES, pH 7.4, 5 mM $CaCl_2$
HEPES	*N*-(2-hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid)
HM	10 mM HEPES, pH 7.4, 5 mM $MgCl_2$
IEM	Immunoelectron Microscopy
IET	Immunoelectron Tomography
LM	Light Microscopy
MAR	Matrix-associated Region
MEM	Maximum Entropy Method
MM	Mounting Medium
NC	Sodium Cacodylate
NE	Nuclear Envelope
NPC	Nuclear Pore Complex
o/n	Overnight
OT	Osmium Tetraoxide
PL	Poly-L-lysine
RPT	Rapid Prototyping Technology
RR	Ruthenium Red
RS	Ringer Solution
RT	Room Temperature
SAR	Scaffold-associated Region
SC	Synaptonemal Complex
SDS/PAGE	Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis
SGI	Silicon Graphics Inc.
SMC	Structural Maintenance of Proteins
TA	Tannic Acid
TEM	Transmission Electron Microscopy
TXHS	0.05% Triton X-100, 30 mM HEPES, pH 7.4, 0.1–0.5 M NaCl, 20 mM KCl, 5 mM $MgCl_2$, 20 mM glycine, 0.02% NaN_3
UA	Uranyl Acetate
WBM	Weighted Back-projection Method
2-D	Two-dimensional
3-D	Three-dimensional

Fluorescence in situ hybridization (FISH) is a technique used to directly visualize specific DNA sequences on morphologically preserved cytological specimens such as metaphase chromosomes, interphase cell nuclei, and extended chromatin fibers or DNA molecules. The general usefulness of radioactive in situ hybridization was greatly hampered by the safety measures required when using radiolabeled probes and the rather long time (up to several weeks) needed for autoradiographic analysis. The development of powerful FISH protocols, in which unspecific hybridization of interspersed repetitive sequences contained within genomic DNA probes is suppressed, allowed for the first time the rapid visualization of single-copy sequences and whole chromosomes, and thus marked a turning point in the experimental and diagnostic application of in situ hybridization. The major advantages of FISH over radioactive methods are increased spatial resolution, speed, probe stability, and the ability to detect multiple chromosomal targets in different colors. Indirect FISH uses hapten-labeled DNA probes in combination with immunocytochemistry (secondary detection reagents). Direct methods use fluorochromes directly coupled to nucleotides in the probe DNA. Probe labeling is most easily accomplished by nick translation or other enzymatic labeling procedures. For hybridization of the modified probe DNA to chromosomes and cell nuclei, both probe and target DNA must be denatured. In the hybridization reaction, complementary single-stranded sequences in the probe and chromosomal target are allowed to reanneal. After posthybridization washing and immunocytochemical detection of in situ bound hapten molecules, a specific fluorescent signal is produced at the hybridization site, which can be viewed by eye through the epifluorescence microscope. Digital imaging and computerized storage of images have largely replaced photography and greatly facilitated data analysis and image handling. However, most importantly the success of FISH experiments depends on the quality of the chromosome preparations and the size of the chromosomal DNA target. When large-insert (>30 kb (kilobase)) clones or complex DNA libraries are used as FISH probes, between 80% and 100% of the target chromosomes carry visible hybridization signals. This percentage drops to only a few percent when 1 kb or less of a single-copy sequence is hybridized. In the past few years several technical advances have expanded FISH applications. Comparative genomic hybridization (CGH) of differentially labeled tester (tumor or patient) and normal reference DNA allows the analysis of all genetic imbalances (chromosomal gains and losses) in a tester genome within a single experiment and without the need to prepare chromosomes from the tester. Combinatorial probe labeling and multicolor FISH are used for the simultaneous detection of 24 (or more) chromosomal targets in different colors, and therefore can provide a comprehensive picture of extensively rearranged tumor karyotypes. The DNA resolution of FISH has been dramatically increased (from several megabases (Mbs) to several kilobases) by hybridization to

extended chromatin fibers and linearized DNA molecules. Fiber FISH and molecular combing allow one to order probes relative to each other, to orient probes within a contig, and to determine the degree of overlap or gap size between different probes. Overall, FISH has become an increasingly popular method with a broad spectrum of applications in cytogenetics, genomics, tumor biology, and many other research areas. It has a bright and colorful future.

1 INTRODUCTION

FISH has become an extremely powerful and widely used experimental method over the past 10–15 years, and has created an entirely new field, molecular cytogenetics. It can be used to localize specific DNA sequences on chromosomes, interphase nuclei, and experimentally extended chromatin fibers or DNA molecules. In situ hybridization techniques were originally developed in the late 1960s,[1,2] at a time when only radioactive labels were available for nucleic acids and cloned DNA probes did not yet exist. Enzymatic labeling of nucleic acids with biotin[3] and other haptens offered several important advantages over radioactive in situ hybridization. Nonisotopically labeled DNA sequences are stable for years and the hybridized probes can be evaluated directly at the microscope without autoradiography. This not only significantly shortens analysis time and avoids hazardous radioactive waste, but there is also something very satisfying about a fluorescing image. The advance of molecular cloning and, more recently, the launch of the human genome project have led to an explosion in the number of DNA probes that are available for in situ hybridization to visualize a chromosome or chromosome region of interest. In addition, FISH applications have been greatly expanded by the development of user-friendly microscope systems that use digital imaging for data acquisition, analysis, and storage.

The principle behind in situ hybridization (and many other molecular techniques) is the ability of complementary single-stranded DNA sequences to specifically reanneal, forming double-stranded DNA (hybrid) molecules. The probe DNA molecules are enzymatically labeled with modified nucleotides. The hapten- or fluorescent-labeled DNA molecules then bind to chromosomes and cell nuclei at the site of specific (homologous) DNA sequences by in situ hybridization. In contrast to the hybridization of nucleic acids in solution, the target DNA sequences are organized by histone and nonhistone proteins into the highly condensed (2000–10 000-fold) interphase or metaphase chromosome structure. This high degree of compaction involving a hierarchy on different levels hinders access of the probe DNA and the hybridization reaction. Therefore, at the theoretical level, many aspects of in situ hybridization procedures still have a largely empirical basis. Briefly, probe DNA and target chromosomes are denatured and the resulting single-stranded DNA molecules are then allowed to reanneal. After various washing and detection steps, a specific fluorescence signal is visible at the chromosomal site of probe hybridization.

Overall, FISH is a surprisingly simple and robust technique which has applications in many different research areas, including clinical cytogenetics, gene mapping and genomics, evolution, and tumor biology. Although FISH methodology is used predominantly for the study of the human genome, FISH techniques have been successfully adapted for use in the study of a wide variety of genomes, from those of yeast to man. In this light, the following protocols may be useful not only for human cytogeneticists but for a wide variety of chromosome researchers.

2 EQUIPMENT FOR DIGITAL IMAGING MICROSCOPY

A typical FISH workstation consists of the following components.[4]

1. A relatively simple upright epifluorescence microscope with objectives, epifluorescence filter sets, and excitation source. Switching between different fluorochromes is achieved by changing filter sets. In routine FISH work, cross-talk between blue, green, and red fluorochromes (i.e. 4′,6-diamidino-2-phenylindole (DAPI), fluorescein isothiocyanate (FITC), and Cy3) imaged with their specific filter sets should be less than 10%. Longpass filters produce brighter single-fluor images but poorer spectral discrimination between fluorochromes. The most commonly used light source that will excite fluorescent dyes from the ultraviolet (UV) into the red region of the spectrum is the high-pressure mercury arc. The projection optics form a real image at the focal plane of the camera.
2. Thermoelectronically cooled charge-coupled device (CCD) cameras with medium format CCD chips are recommended for FISH imaging. A host computer is needed for camera control, image acquisition, image processing, image display, and storage of data. Digital imaging benefits from a very fast computer with 40–60 Mb of RAM (random access memory). Large image files require a hard disk capacity of about 2 GB and a back-up system.
3. Software packages for image acquisition, processing, and data analysis are available from different

companies, i.e. Applied Imaging, Leica Microsystems Imaging, Meta Systems, Oncor, PSI, Vysis, and others. Since FISH software packages can be quite costly and usually not all of the functions are needed in a routine laboratory, it is strongly recommended that software is tested in the lab using typical chromosome preparations and experimental conditions. Typically a series of images is taken through different filters. These gray-scale source images have to be merged and pseudo-colored. Sometimes the image background needs to be cleaned up and/or the specific signal needs to be enhanced. For gene mapping, it is very useful to convert DAPI fluorescence of a chromosome into a G-banding pattern for chromosome identification. Furthermore, it should be possible to measure the chromosomal location (fractional chromosome length) of FISH signals and to (manually) arrange chromosomes into a karyotype.

3 DNA PROBES

The various applications of FISH would not be possible without the general availability of DNA probes for specific chromosomes or chromosome regions of interest. Today a large number of different types of probes for human and other important model genomes are available, either commercially or from various genome resource centers and research laboratories. The choice depends mainly on the specific requirements of the experiments and on the laboratory expertise in molecular cytogenetics. For example, satellite DNAs are ideal probes for beginners, because they do not require suppression hybridization, and therefore are much easier to use than genomic probes containing interspersed repetitive elements. The efficiency of hybridization and the fluorescence at the hybridization site largely depend on the size of the target DNA sequences on the chromosome. Hybridization sites spanning several kilobases should be detectable without sophisticated equipment.

3.1 Satellite and Localized Repeat DNAs

Satellite DNA families are based on tandemly repeated monomers or higher-order repeating structures consisting of diverged monomers. Since satellite-DNA-containing chromosomal regions are not interspersed with other cross-hybridizing sequences, and usually span several hundred kilobases to several megabases, they are easily detected by FISH without suppression hybridization. This means that the prehybridization step (see standard FISH protocol in section 5) can be omitted. Chromosome-specific satellite DNAs or rRNA gene clusters produce very intense and compact signals in both metaphase and interphase cells (Figure 1d, g). One of the most thoroughly studied repetitive DNA families is α-satellite DNA, which is found at the centromeric regions of all human and primate chromosomes.[5–7] Chromosome-specific α-satellite subsets have been described for the majority of human chromosomes and are widely used in routine cytogenetic laboratories, i.e. for aneuploidy studies.

3.2 Chromosome-specific DNA Libraries

DNA libraries represent complex mixtures of DNA sequences that are derived from a single chromosome type and, therefore, specifically paint the target chromosome by FISH (Figure 1c, e; Figure 2a). Whole-chromosome painting probes of high quality have been constructed from flow-sorted human and other mammalian chromosomes[8–10] and by chromosome microdissection.[11] In addition, microdissection has been used to generate region-specific DNA libraries.[12]

3.3 Region-specific Large-insert Clones

Large-insert probes, such as cosmids, λ phages, bacterial artificial chromosomes (BACs), P1-derived artificial chromosomes (PACs), and YACs, produce high-intensity site-specific FISH signals on 80–100% of the hybridized chromosomes and cell nuclei. Our lab has created a large set of (to date) 2000 YAC probes with approximately one YAC every 3–5 cM (centimorgan) spaced evenly over the entire human genome covering all human chromosome bands.[13] These YACs have been well characterized by polymorphic genetic markers and FISH-mapped on human metaphase chromosomes. This standard set of cytogenetically and genetically anchored YACs allows the rapid integration of genetic and cytogenetic maps. It is an extremely flexible tool for use in a wide variety of FISH applications, such as the study of pathological and evolutionary chromosome rearrangements (Figure 1a–e; Figure 2b, c). Similar molecular cytogenetic resources have been generated for the mouse and other experimental animals.[14,15] For most FISH experiments, purification of the clone insert is not necessary. Labeled vector sequences in the DNA probe do not hybridize appreciably to human chromosomes. Nonspecifically formed (vector–chromosome) hybrid molecules are dissociated during the posthybridization washings (see section 5.3).

3.4 Total Genomic DNAs

In situ hybridization with total (genomic) nuclear DNA was first applied in plant cytogenetics for identifying parental chromosomes in interspecific plant hybrids and

Figure 1 Clinical cytogenetic applications of FISH: detection of structural and numerical chromosomal aberrations. (a) Triplication of subtelomeric sequences in the long arm of chromosome 1. The red yeast artificial chromosome (YAC) produces similar hybridization signals on both chromosomes. The green YAC produces three double-dot hybridization signals on the aberrant chromosome. (b) Hybridization of YACs specific for the subtelomeric regions on the short (green) and long (red) arms of chromosome 6, respectively. (c) Paracentric inversion on the X chromosome of a female patient. Both X's are painted with a chromosome-specific DNA library (green). The red YAC produces a single hybridization signal on the short arm of the normal X and a split signal on the long and short arms of the inverted X. (d) Balanced translocation between chromosomes 2 and 12. The green α-satellite probe hybridizes to the centromere of the normal chromosome 2 and the translocated chromosome der(2). The red YAC hybridizes to the proximal long arm of the normal chromosome 2 and to the translocated chromosome der(12). The hybridized probes flank the breakpoint on chromosome 2. (e) The same X inversion as seen in (c) during interphase. Note the split YAC hybridization signal in the upper X-chromosomal domain. (f) Asynchronous replication of subtelomeric sequences. The green 4qter YAC produces two hybridization doublets, indicating that the delineated homologous segments are fully replicated. The red 10qter YAC produces one unreplicated singlet and one replicated doublet hybridization signal, consistent with asynchronously replicating homologous chromosome regions. (g) Hybridization of five differentially labeled α-satellite DNAs specific for chromosomes 5, 6, 8, 20, and X on a normal female interphase nucleus.

Figure 1 (*Continued*)

following the introgression of alien chromosomes.[16,17] More recently comparative hybridization of genomic tumor DNA versus normal reference DNA on normal human metaphase spreads has been used to assess chromosome gains and losses in tumor tissues.[18]

3.5 cDNAs

Complementary DNAs (cDNAs) represent only the transcribed (exonic) sequences of genes and contain as little as several hundred base pairs (bps) of target sequence. The hybridization efficiency is low and depends on both cDNA size and intron/exon structure of the targeted gene. FISH mapping of cDNAs and small-insert (<1 kb) plasmid clones requires special expertise and/or digital imaging microscopy.

4 PROBE LABELING

Two major alternatives exist for fluorescent hybridization methods: direct and indirect. In the direct method, fluorescent reporter molecules are incorporated directly into the DNA probe. A wide variety of fluorescent deoxynucleotide triphosphates (dNTPs) can be used for direct labeling, i.e. FITC-, Texas Red-, Rhodamine-, Cy3-dUTP, and many more. Since the probe–target DNA hybrids resulting from in situ hybridization are immediately visible under the microscope, direct methods are very fast. They offer other advantages, such as low background fluorescence and increased possibilities for multicolor analysis. On the other hand fluorescent probes are prone to photobleaching during preparation and hybridization. In the indirect method, hapten reporter molecules, i.e. biotin- or digoxigenin-dUTP, which are introduced into the DNA probe, are detected by affinity cytochemistry after the hybridization reaction. Fluorescent (strept)avidin molecules bind specifically to biotin-labeled probe–target hybrids. Fluorescent anti-digoxigenin antibodies are used to detect digoxigenated probes. The fluorescence signals of indirectly labeled probes may be up to ten times brighter than those produced by direct methods. In addition, small hapten molecules such as biotin are more efficiently incorporated into DNA than most fluorescent dNTPs. Thus, indirect labeling may be preferable for most FISH applications. Haptenized and, to a lesser extent, fluorescent probes can be stored at −20 °C for many years without compromising performance.

Different enzymatic labeling procedures can be used to introduce modified dNTPs into DNA probes, i.e. nick translation, random priming, and polymerase chain reaction (PCR). Nick translation[19] is recommended for labeling double-stranded DNA molecules because large amounts of DNA can be labeled and most FISH experiments require high probe concentrations. Random priming[20] has the advantage that small amounts of DNA and single-stranded probes can be efficiently labeled. PCR is a very convenient and fast method for labeling PCR-amplifiable large-insert probes and DNA libraries.

4.1 Nick Translation

The DNA template can be supercoiled or linear. After nicking the DNA with DNase I, the 5′–3′ exonuclease activity of DNA polymerase removes nucleotides and the DNA polymerase activity replaces the excised nucleotides with dNTPs from the reaction mixture, including the labeled nucleotide. The procedures for incorporating biotin, digoxigenin, or fluorochromes are nearly identical. The kinetics of the reaction reaches an optimum after 30–60 min. The final size of the nick-translated probe DNA fragments is very important. Labeled probe sequences which are larger than 500 bp have difficulty penetrating the specimen and a tendency

Figure 2 Comparative genome mapping by FISH. (a) Hybridization of painting probes specific for human chromosome 5 (green) and 17 (red) on human (HSA) and gorilla (GGO) metaphase spreads. Note the evolutionary rearrangement (translocation) involving the gorilla homologs of HSA 5 and 17. (b) Hybridization of a subtelomeric YAC from the long arm of human chromosome 3 on the Old World monkey *Presbytis cristata* (PCR). Note the split hybridization signal on the monkey homolog of HSA 3. The hybridized YAC spans an evolutionary chromosome breakpoint. (c) Hybridization of the same YAC on great ape and monkey homologs of HSA 3. Orangutans (PPY) and humans show the same hybridization patterns. In gorilla and Old World monkey the YAC delineates paracentric inversions involving the same distal but different proximal breakpoints. This indicates the occurrence of convergent chromosomal mutations. Insets show converted DAPI images (G bands).

to stick nonspecifically to both the glass and the cellular material, resulting in high background which obscures the signal. Sequences shorter than 100 bp do not hybridize efficiently under routine conditions of stringency.

Mix on ice, in a microcentrifuge tube:

DNA (in liquid format)	1 μg
10 × nick-translation buffer (see Appendix 1)	5 μL
0.1 M β-mercaptoethanol (BME) (see Appendix 1)	5 μL
10 × cold dNTP solution (0.5 mM each of dATP, dCTP, dGTP)	5 μL
10 × 1 : 3 labeled dUTP/cold dTTP solution (0.125 mM labeled dUTP, i.e. biotin-16-dUTP or digoxigenin-11-dUTP, and 0.375 mM dTTP) A labeling density of one modified nucleotide at approximately every 20–25th position in the nick-translated DNA is optimal for most FISH experiments.	5 μL
10 × DNase I (DNase stock with an activity of 10 U μL^{-1} is diluted 1 : 3000–1 : 4000 with ddH_2O (double-distilled water)) Optimal DNase concentration must be determined by titration, as the size distribution of the probe depends on the amount of enzyme added. Each new stock of DNase I should be tested to determine the appropriate working concentration.	5 μL
DNA polymerase I (5 U μL^{-1})	1.3 μL
ddH_2O	Add as needed to achieve final reaction volume of 50 μL

If larger amounts of DNA (up to 5 μg) need to be labeled, the reaction volumes can be scaled up to 250 μL.

Incubate the reaction mixture for 2 h at 15 °C. The time of incubation should not be shortened; at least 2 h are necessary for optimal incorporation, as the initial incorporation rate of modified nucleotides is less than that of unsubstituted dNTP.

Check the size of the nick-translated DNA fragments on a 1.5% agarose gel, along with suitable size markers (0.1–1 kb range). If the DNA fragments are still too large, add a second aliquot of DNase (optional) and incubate for another 30–60 min at 15 °C.

When the majority of the fragments are between 100 bp and 500 bp in size, terminate the reaction by adding stop buffer (1.25 μL 0.5 M EDTA (ethylenediamine tetraacetic acid) and 0.5 μL 10% SDS (sodium dodecyl sulfate) (see Appendix 1) to the 50 μL of nick-translation mixture. Heat tube to 68 °C for 10 min.

For most types of probes, i.e. satellite DNAs, DNA libraries or large-insert clones, purification of the labeled probe DNA is not necessary. Simple ethanol precipitation is sufficient. For small single-copy DNA probes, purification by centrifugation through Sephadex G-50 or commercially available columns is recommended to remove unincorporated haptenized or fluorescent nucleotides.

4.2 Polymerase Chain Reaction

Degenerate oligonucleotide primed (DOP)[21] and inter-Alu[22] PCR are widely used to amplify complex DNA probes from large-insert clones, i.e. PACs and YACs, and flow-sorted or microdissected DNA libaries. Alu PCR amplifies only sequences located between Alu repeats in the human insert, whereas DOP PCR amplifies vector (bacterial or yeast) sequences along with the entire insert. However, since DOP PCR products are much more complex than Alu PCR products, they usually generate better FISH signals. PCR-generated probes can be efficiently labeled by re-amplification of the DOP or Alu PCR product, in reactions where dTTP is partially replaced by modified dUTP. Since optimal PCR conditions are largely dependent on the DNA template and primer(s), the DOP PCR labeling protocol described here is, by necessity, generalized.

Mix on ice, in a centrifuge tube:

Template DNA (in liquid format)	200–400 ng
10 × *Taq* polymerase buffer (see Appendix 1)	5 μL
25 mM $MgCl_2$	4 μL
20 pM μL^{-1} DOP primer (5′-CCG ACT CGA GNN NNN NAT GTG G-3′)	20 μL
2 mM dATP	3.75 μL
2 mM dCTP	3.75 μL
2 mM dGTP	3.75 μL
2 mM dTTP	1.25 μL
1 mM biotin-16-dUTP (or other labeled dUTP)	0.5 μL
Taq polymerase	0.5 μL
ddH_2O	Add as needed to achieve final reaction volume of 50 μL

After an initial denaturation at 94 °C for 1 min, 30 cycles are carried out with denaturation at 94 °C for 1 min, annealing at 56 °C for 1.5 min, and extension at 72 °C for 2 min followed by incubation at 72 °C for 10 min.

5 IN SITU SUPPRESSION HYBRIDIZATION (STANDARD FLUORESCENCE IN SITU HYBRIDIZATION PROTOCOL)

Ubiquitously repeated sequences, i.e. of the Alu and L1 families, occur approximately 900 000 and 100 000 times in the human genome respectively.[23] Since interspersed repeats are present at least once in every 5 kb of genomic DNA, complex DNA libraries, large-insert clones, and most other DNA probes contain a significant number of repetitive elements that can cross-hybridize with closely related repeats throughout the entire genome. Consequently, these probes will not only hybridize to their specific target DNA sequences but to all chromosomes, yielding ambiguous FISH signals. To prevent such unspecific hybridization, repetitive DNA sequences in the probe DNA are blocked by prehybridization with unlabeled total genomic DNA or repetitive Cot-1 DNA.[24–26] The fast reassociating (Cot-1) fractions of genomic DNA probes reanneal under the appropriate (pre)hybridization conditions, and thus mainly single-copy DNA sequences in the hybridization mixture remain single-stranded and can hybridize to their target sequences on chromosomes. The following is a detailed protocol for suppression hybridization that has been optimized for the fluorescent detection of single-copy DNA sequences.

5.1 Hybridization Mixture

Nick-translated DNA probes have a final concentration of approximately 20 ng μL^{-1} (in nick translation buffer), PCR-labeled probes one of approximately 100 ng μL^{-1} (in *Taq* polymerase buffer). First, differentially labeled probes which are to be hybridized on the same specimen are precipitated together with an approximately 50-fold excess of Cot-1 competitor DNA (Gibco BRL) or a 500-fold excess of fragmented (100–500 bp) total genomic DNA, and a 50-fold excess of fragmented salmon sperm DNA (see Appendix 1) which is used as a carrier. The optimal DNA concentrations in the hybridization mixture (30 µL for a whole slide) depend mainly on the probe types. For large-insert PAC and YAC clones, 10–20 ng μL^{-1} in the hybridization mixture (or 300–600 ng per slide) are recommended. For small-insert plasmid clones and cDNAs, higher probe DNA concentrations of 20–50 ng μL^{-1} may be superior. For very complex (painting) probes, such as chromosome- or arm-specific DNA libaries, 5–10 ng μL^{-1} in the hybridization mixture (or 150–300 ng per slide) usually yield good results. The probe concentration in the hybridization mixture affects the rate at which the first few base pairs are formed (nucleation reaction). The adjacent base pairs are formed afterwards. Since the nucleation reaction is the rate-limiting step in hybridization, the higher the concentration of the probe, the higher the reannealing rate.

As a rule, the higher the proportion of repetitive elements present in the probe DNA, the more the competitor DNA that is needed. Probes containing mainly interspersed repeats and only few single-copy sequences are difficult to hybridize and yield inferior FISH signals. As might be expected, if too little competitor DNA is added, background signals from the interspersed repetitive elements will not be effectively suppressed. Vice versa, the addition of too much competitor DNA will reduce the signal intensity as well as the background.

In the following example, a YAC and a chromosome-specific DNA library will be hybridized together on the same slide.

	Stock	Amount required
Biotinylated (nick-translated) YAC DNA	20 ng μL^{-1}	20 µL (400 ng)
Digoxigenated PCR-labeled) DNA library	100 ng μL^{-1}	2 µL (200 ng)
Cot-1 DNA (Gibco BRL)	1 µg μL^{-1}	30 µL (30 µg)
Salmon sperm DNA	10 µg μL^{-1}	3 µL (30 µg)

Precipitate the DNA as usual with 1/20 volume 3 M NaAcetate (see Appendix 1) and 2 volumes 100% EtOH (p.a.) in a microcentrifuge tube. Mix well and keep the tube for at least 30 min at −70 °C or overnight at −20 °C.

Spin for 30 min at 15 000 rpm at 4 °C. Discard the EtOH and dry the pellet in a vacuum system or a 37 °C heating block.

Add 15 µL of deionized formamide (see Appendix 1) and shake at 37 °C for at least 15 min to resuspend the probe DNA. Then add an equal volume of 2 × hybridization mixture (20% dextran sulfate, 4 × SSC (standard saline citrate)) (see Appendix 1) and shake vigorously for at least 15 min. Dextran sulfate is very hydrophilic. The consequence is that macromolecules such as DNA have no access to the hydrating water, which leads to an apparent increase in probe concentration and consequently higher hybridization rates.

Routine conditions of stringency are 50% formamide, 10% dextran sulfate, 2 × SSC in the hybridization mixture. Occasionally, stringency conditions may need to be increased (e.g. for highly repetitive satellite DNAs or if a single-copy probe also cross-hybridizes weakly to a second site) or decreased (e.g. if trying to hybridize with a very short oligonucleotide probe or with a complex probe from a related species). Hybridization stringency can be increased by increasing the incubation temperature or the formamide concentration, or by decreasing the salt (SSC)

concentration in the hybridization mixture. Usually, stringency is increased by using 60–70% formamide in the hybridization mixture, or decreased by using only 20–30% formamide.

Denature the hybridization mixture (containing the probe DNA) at 80 °C for 10 min. Centrifuge the probes for 2–5 s in order to pellet the condensed water.

To allow reannealing of repetitive DNA fractions, incubate the tube with the denatured competitor and probe DNA at 37 °C for at least 15 min (but not longer than 1 h).

Place the preannealed DNA probe (30 μL) on the denatured slide and cover with a coverslip. Seal the edges with rubber cement and incubate overnight (or longer) at 37 °C in a moist chamber.

5.2 Slide Preparation

The quality of the chromosome preparations is a very critical parameter for the efficiency of FISH. Metaphases can be prepared from any (exponentially) growing cell culture, i.e. short-term blood cultures, bone marrow, fibroblasts, lymphoblastoid cell lines, and tumor cells.[27] The most widely used procedure for the preparation of high-quality chromosomes involves phytohemagglutinin stimulation of T lymphocytes of human peripheral blood in culture and metaphase arrest by adding the spindle poison colcemid shortly before harvesting. Harvested cells are swollen in hypotonic solution (50 mM KCl at 37 °C for 5–10 min) and fixed in a 3 : 1 mixture of ice-cold methanol–acetic acid. Chromosome suspensions can be stored at −20 °C for several months without compromising performance.

To prepare slides, put one drop of chromosome suspension on a very clean glass slide. Ambient temperature and humidity influence how quickly the fixative dries on the slide. Slides which dry too quickly have very low contrast and the chromosomes have a tendency to come off the slide when denatured. Slides which dry too slowly appear refractile under the microscope and may exhibit poor morphology after denaturation. Chromosome preparations for FISH should be between one day and one month old. Extra slides can be stored in a desiccating box for several months at −20 °C.

Rinse the slides in 2 × SSC, pH 7.0 for 5 min. Treat them for at least 30 min at 37 °C in 2 × SSC containing 100 μg mL^{-1} RNase A (see Appendix 1). Then wash slides 3 × 5 min in 2 × SSC, pH 7.0. RNase treatment serves to remove endogenous RNA which may hybridize with homologous probe DNA sequences, forming RNA–DNA hybrids. This improves the signal-to-noise ratio in hybridization to DNA targets.

Incubate the slides with pepsin for 10 min (but not much longer) at 37 °C in 0.05% (w/v) pepsin powder in 0.01 M HCl. Wash slides 2 × 5 min in 1 × PBS (phosphate-buffered saline) (see Appendix 1) and then 2 × 5 min in 1 × PBS containing 50 mM $MgCl_2$. Fix slides with 1% formaldehyde, 1 × PBS, 50 mM $MgCl_2$ for 10–60 min at room temperature. Wash the slides thoroughly in PBS. Pepsin and other proteases (i.e. proteinase K or pronase) increase accessibility by digesting chromosomal proteins that package the target DNA. Since metaphases and nuclei have the tendency to come off the slides after prolonged protease treatment, refixation of the slides with formaldehyde is recommended.

Dehydrate slides in an ethanol series (70%, 85%, 100%) for 5 min each and air-dry. Place 200 μL of denaturation solution, consisting of 70% deionized formamide and 2 × SSC (see Appendix 1), on each slide and cover with a coverslip. Place in a 90 °C oven for approximately 60 s. Shake off coverslip and put slide immediately in ice-cold 70% ethanol. Dehydrate again in an ice-cold ethanol series (70%, 85%, 100%). After air-drying, the slides are ready for in situ hybridization.

Alternatively, chromosomes may be denatured in a water bath at 70 °C by immersing the slide for 2–5 min in a Coplin jar with 70% formamide, 2 × SSC. This may be more accurate and easier to standardize than the procedure described above, but it also creates more waste. Formamide is a proven carcinogen and teratogen. Denaturation of chromosomal target DNA can also be achieved with extremes of alkaline pH; however, heat (formamide) denaturations have become popular because of their experimental reproducibility and greater effectiveness.

Poorly fixed chromosomes may over-denature, resulting in a hollow, puffy apperarance under the phase contrast microscope, and/or come off the slide during denaturation in formamide. Inferior grade formamide may also destroy much of the chromosomal morphology. Denaturation inevitably leads to loss of morphology, so in practice a compromise must be found between hybridization signal and chromosome morphology. Variations in time and temperature should be evaluated to find the best conditions for denaturation.

5.3 Hybridization and Signal Detection

Pipette 30 μL of denatured and pre-annealed probe mixture on the prewarmed slide (15 μL for half a slide). Cover the slide with a coverslip, being careful not to trap air bubbles, and seal the edges with rubber cement.

Hybridize overnight in a moist chamber at 37 °C. Longer hybridization times (2–7 days) may be required for probes which do not show 100% sequence identity with the chromosomal target.

Wash the slides for 3 × 5 min at 42 °C in 50% formamide, 2 × SSC (see Appendix 1) and then 2 × 5 min at 60 °C in 0.1 × SSC. To lower the stringency, increase the salt concentration (i.e. to 0.5–2 × SSC) of the last two

washes. To increase the stringency, use 65% formamide, 2 × SSC for the first three washes. However, hybridization rather than stringent washing is recommended. The washing solutions are pre-warmed in different water baths. The Coplin jar with slides and pre-warmed washing solution is agitated on a platform shaker.

The probe DNA hybridizes not only to the target DNA but also nonspecifically to sequences which bear partial homology to the probe sequence. Since such nonspecific hybrids are less stable than perfectly matched DNA hybrids, they can be dissociated by posthybridization washes of various stringencies.

Directly labeled probes can be viewed immediately after the posthybridization washes. Secondary incubations and washes are required for the visualization of haptenized DNA probes. Prior to incubation with secondary reagents, slides should be blocked by treating with 5% bovine serum albumin (BSA) in 4 × SSC, 0.1% Tween 20. Incubate slides in a Coplin jar with fresh blocking solution (see Appendix 1) for at least 30 min at 37 °C. Blocking prevents unspecific antibody binding and reduces background.

Dilute fluorescent (strept)avidin and anti-digoxigenin antibodies, i.e. FITC-avidin and Cy3-conjugated anti-digoxigenin, 1 : 800 and 1 : 200, respectively (or according to recommendations of the supplier) in 1% BSA, 0.1% Tween 20, 4 × SSC (see Appendix 1). Cover the slides with 200 µL of detection solution and a coverslip. Incubate in a moist chamber in the dark at 37 °C for 30 min.

Shake off the coverslips and wash the slides 3 × 5 min in a Coplin jar with 0.1% Tween 20, 4 × SSC (see Appendix 1) at 42 °C.

To visualize chromosomes and cell nuclei, counterstain the slides for 1–2 min with 1 µg mL^{-1} DAPI in 2 × SSC. Wash the slides thoroughly with distilled water, air-dry and then mount them with antifade mounting medium (see Appendix 1). 1,4-Diazobicyclo[2.2.2]octane (DABCO) retards fading of the fluorescence after exposure of the slides to fluorescence light.

Large-insert clones and DNA libraries should produce specific fluorescence signals, which are clearly visible by eye through the microscope. Small probes (<5 kb) and cDNAs may require immunological signal amplification to be seen by eye. The fluorescence of (strept)avidin–biotin complexes can be enhanced by using biotinylated goat anti-avidin antibody followed by another incubation with fluorescent (strept)avidin. This ''sandwich technique'' for signal amplification of biotinylated probes can be repeated several times.[28] Digoxigenated DNA probes binding fluorescent mouse anti-digoxigenin antibody can be amplified with a second layer of fluorescent rabbit anti-mouse antibodies and, if necessary, with a third layer of fluorescent goat anti-rabbit antibodies. FISH signal intensities can be even more dramatically enhanced by the tyramide method.[29] Peroxidase-conjugated (strept)avidin or anti-digoxigenin antibody is applied as a first layer. In a second step, this peroxidase uses fluorescent or biotinylated tyramide as a substrate to deposit many fluorochrome or biotin molecules in the immediate vicinity of the in situ bound enzyme. These can be evaluated either directly or after a third incubation with fluorochrome-labeled (strept)avidin. As a general rule, every amplification level not only enhances the signal, but also the background intensity. Because of the high sensitivity of digital cameras, use of electronic image enhancement is arguably preferred over immunocytochemical signal amplification.

Proper chromosome identification requires the simultaneous observation of chromosome bands and hybridization signals. A large number of widely different fluorescent banding procedures have been proposed, including FISH of interspersed Alu elements, which are enriched in R bands;[30] saline heat treatment followed by acridine orange staining;[31] and various counterstain-enhanced banding methods, i.e. actinomycin/DAPI staining for G bands or distamycin A/chromomycin A3 for R bands.[32] In general, the resulting chromosome banding patterns are just sufficient to identify chromosomes and to map probes at a low resolution (250–300 band level). Fluorescent replication banding of BrdU-substituted chromosomes tends to produce a more accurate banding after hybridization.[33]

Specialized FISH software allows the conversion of the plain DAPI fluorescence of a chromosome into a G-like banding pattern (Figure 2c; Figure 3c). In addition, the cytogenetic location of a hybridization signal can be expressed as the fractional length (FLpter) of the total chromosome relative to the short-arm telomere.[34] Many FISH programs infer the cytogenetic band location of a hybridization signal from the FLpter measurement. In this context it is important to note that varying degrees of chromosome condensation can lead to discordances between FLpter values and band assignments. Nevertheless, both digital banding and FLpter measurements are very straightforward and now used in most laboratories.

6 MULTICOLOR FLUORESCENCE IN SITU HYBRIDIZATION

One of the major advantages of FISH is the possibility of simultaneously detecting multiple DNA targets on the same metaphase in different colors. Using standard experimental conditions and FISH workstations, one probe may be detected with a green fluorescent dye, a second probe with a red dye, while the chromosomes

Figure 3 Multicolor FISH analysis of a tumor metaphase spread. (a) Spectral karyotype. Note the enlarged chromosome 2 (large arrow) and the additional chromosome 2 material (small arrow) on the long-arm tip of chromosome 16. (b) Spectral image and (c) converted DAPI image of the respective metaphase spread. Despite inferior tumor metaphase quality, the rearranged chromosomes are easily identified.

are counterstained in blue with DAPI. The three different colors are discriminated with the aid of specific filter sets. In the past few years, an increasing number of spectrally resolvable fluorochromes, ranging from the visible blue to the near infrared, has been developed for the fluorescent detection of DNA probes in multicolor FISH experiments. By combinatorial probe labeling, many more DNA targets can be discriminated than the number of distinguishable fluorochromes. Combinatorial labeling involves the introduction of two or more fluorochromes into a single probe in approximately equal amounts. Different probes are characterized by different combinations of fluorochromes. The maximum number of useful Boolean combinations of n fluors is $2^n - 1$. The 31 possible combinations for five fluorochromes allow one to uniquely identify all 24 human chromosome types.

There are two strategies for analyzing combinatorial multicolor FISH images. The multiplex fluorescence in situ hybridization (M-FISH) procedure is based on highly specific epifluorescence filter sets that have very narrow bandwidths, compared with standard filters, and, therefore, give a high degree of discrimination between all possible fluor combinations.[35] Images are acquired separately for each of the five fluorochromes and for DAPI counterstaining, then are overlaid, generating a composite image. Specialized software is used to pseudocolor each chromosome according to its fluorochrome composition. In contrast, spectral karyotype analysis (SKY) is significantly different from conventional epifluorescence microscopy and does not rely on fluorochrome-specific optical filters. It combines optical microscopy, Fourier spectroscopy, and CCD imaging. Discrimination of multiple fluorochromes is achieved by measuring a discrete fluorescence emission spectrum (representing a sequence of intensities at many different wavelengths) simultaneously at all image points after a single exposure. A filter set with broad emission bands allows the simultaneous excitement of all dyes and measurement of their emission spectra. Specialized software then classifies each chromosome, by assigning the same pseudocolor to all pixels with the same emission spectrum (Figure 3).[36]

PCR-amplifiable DNA libraries from microdissected or flow-sorted chromosomes are used as a starting material. Table 1 shows a combinatorial labeling scheme for 24-color FISH. Spectrum Orange, Texas Red, and Rhodamine are directly incorporated by PCR. Cy5-avidin and Cy5.5-conjugated antibodies are used as secondary reagents to detect biotinylated and digoxigenated probes. For each probe, one to four separate PCR labeling reactions are necessary, each with a fluorescent, biotinylated or digoxigenated dUTP.

To hybridize one slide, take 5 μL of PCR-labeled DNA for each DNA library and each color. For example, 5 μL of each Texas Red®-, rhodamine-, and biotin-labeled chromosome 1 library are taken. The final probe mixture consists of 57 aliquots or 285 μL. Then add 50 μL Cot-1 DNA, 1 μL salmon sperm DNA, 20 μL 3 M NaAcetate (see Appendix 1), 1 mL ice-cold EtOH, and precipitate the DNA at −20 °C overnight. Spin in a microcentrifuge for 45 min at 15 000 rpm and discard the supernatant. Wash the DNA pellet in 1 mL 70% EtOH and spin again. Then allow the precipitated DNA pellet to air-dry in the dark.

Resuspend the DNA pellet in 30 μL hybridization mixture (50% formamide, 10% dextran sulfate, 2 × SSC). In order to resuspend this large amount of probe DNA, it may be necessary to agitate the hybridization mixture on a shaker at 37 °C for several hours. Denature the hybridization mixture for 10 min at 80 °C and incubate it for approximately 30 min at 37 °C.

After the pre-annealing step, put the probe mixture on the denatured chromosome preparation. Hybridization should be done for several days (up to one week) at 37 °C in a moist chamber in the dark.

Posthybridization washes should be done, using standard conditions of stringency (see section 5.3). Then incubate the slides with Cy5-avidin and mouse anti-digoxigenin antibody, diluted 1 : 500 and 1 : 200, respectively, in 1% BSA, 0.1% Tween, 4 × SSC. After washing the slides 3 × 5 min with 0.1% Tween, 4 × SSC, incubate slides with Cy5.5-conjugated anti-mouse IgG, diluted 1 : 200 with detection buffer (see Appendix 1). All incubation and washing steps must be performed in the dark. Finally, counterstain the slides with DAPI and mount them.

Spectral analysis requires a SpectraCube system (Applied Spectral Imaging). The imaging system is attached to an epifluorescence microscope. It consists of an optical head with a Sagnac common path interferometer. The interferogram of each pixel is analyzed by Fourier transformation, to create a spectrum. This spectrum is imaged with a CCD camera. A spectral-based classification algorithm identifies the multiple different spectra in the acquired image and highlights them in RGB (red/green/blue) classification colors.[36,37] By computer classification of spectra, the spectrally overlapping (combinatorially labeled) 24 DNA libraries can be resolved

and the entire genome can be analyzed simultaneously on the basis of the differential display of all human chromosomes.

Multicolor karyotyping is a very powerful screening method for complex interchromosomal rearrangements, i.e. in tumor cells (Figure 3). It can decipher extensively rearranged karyotypes that cannot be fully characterized by classical chromosome banding or conventional FISH. The limit of sensitivity for karyotype analysis with combinatorial probe labeling and currently available M-FISH or SKY systems is in the order of several megabases and, thus, lower than that with standard (three-color) FISH. An alternative approach to increase the number of detectable chromosomal targets beyond the number of spectrally resolvable fluorochromes is ratio labeling. For example, all 24 human chromosomes can be discrimated by a combination of only four fluorochromes at different ratios.[38]

7 COMPARATIVE GENOMIC HYBRIDIZATION

CGH is a method to screen a genome for DNA-sequence copy-number variation.[18,39] Tester DNA, isolated from a tumor or a patient, and normal (human) reference DNA are labeled with different fluorochromes, i.e. FITC for the tester DNA and Cy3 for the reference DNA, and hybridized together on normal metaphase spreads under suppression conditions. Hybridization of tester DNA from a chromosomally balanced genome results in a more or less uniform staining of the target chromosomes with both colors. Regions of gain and loss of DNA sequences in a tumor change the relative amounts of tester and reference DNA bound at the respective chromosomal loci and can be identified by measuring the ratio of intensities of the two fluorochromes (Figure 4). Amplifications and deletions in the test sample should be visible as higher and lower green fluorescence intensity relative to the red fluorescence intensity of the reference DNA. Large chromosomal imbalances, i.e. loss or gain of an entire chromosome, lead to marked differences in the hybridization profile of the target chromosome on the hybridized normal metaphase spread and should be visible by eye through the microscope. Specialized CGH software, which integrates the green-to-red fluorescence intensities and calculates the ratio along the hybridized chromosomes (Figure 4b), allows the detection of smaller regional changes involving gain or loss of one copy of approximately 10 Mb DNA. Of course, high-level amplifications, i.e. of certain oncogenes, yield a much higher DNA resolution of CGH. Most importantly, in contrast to classical tumor cytogenetics, CGH does not require tumor metaphase spreads. Karyotype analysis in solid and many other tumor types has been hampered by low mitotic index and poor metaphase quality. A single CGH experiment provides comprehensive information on genetic imbalances. However, it cannot detect balanced chromosome rearrangements such as translocations and inversions. In this light, multicolor FISH and CGH are complementary techniques.

If possible, total genomic tumor and reference DNA should be used for CGH experiments. High-molecular-weight DNA is prepared according to standard procedures.[40] One milligram of tissue yields approximately one microgram of genomic DNA. When only small amounts of fresh tumor tissue or archival tumor material are available, a DNA template is generated by DOP PCR amplification.[21,41]

Tumor DNA is labeled by standard nick translation with biotin and detected with FITC-avidin. Reference DNA is labeled with digoxigenin and detected with Cy3-conjugated anti-digoxigenin antibody. Direct labeling is also possible. The optimum probe-fragment-size distribution after nick translation ranges from about 500 bp to 2000 bp. For CGH, the probe DNA fragments should be somewhat larger than for standard FISH experiments (200–500 bp) in order to obtain uniform and intense hybridization on chromosomes.

Samples (100 ng) of each biotinylated tumor and digoxigenated reference DNA are combined with 50–100 μg unlabeled Cot-1 DNA. The precipitated probe DNA is resuspended in 50% formamide, 10% dextran sulfate, 2 × SSC.

Following denaturation of probe and slides, comparative hybridization is performed for 2–3 days at 37 °C in a moist chamber. The slides are washed and probes detected with secondary reagents (see section 5.3). The hybridization profiles are evaluated by specialized CGH software.

8 (ULTRA) HIGH-RESOLUTION FLUORESCENCE IN SITU HYBRIDIZATION

Standard FISH techniques are capable of resolving sequences separated by two or more megabases on metaphase chromosomes.[34] Hybridization on less condensed interphase nuclei further increases the resolution to around 100 kb. The average interphase distance between different probe signals correlates with physical distances up to 1–2 Mb.[42,43] Interphase mapping allows the order and relative proximity of sequences which are closely juxtaposed on the same chromosomal region, and therefore cannot be resolved on metaphase chromosomes, to be determined. Interphase

Figure 4 CGH. (a) Schematic representation of the CGH approach. Amplification of a DNA segment (in the proximal long arm) enhances the green-to-red fluorescence ratio of tumor DNA versus reference DNA on the respective chromosome and is shown in black. Conversely, deletion of the distal long arm in the tumor decreases the green-to-red fluorescence ratio of the target region and is shown in white on the reference chromosome. The mean ratio (thick line) plus/minus one standard deviation (thin lines) are shown for the entire chromosome from pter to qter. (b) Copy-number karyotype of a patient with constitutional chromosome aberration. The baseline value (1) representing the mean green-to-red ratio for the entire metaphase is shown in a solid line and ratios of 0.75 (loss bar) and 1.25 (gain bar) as dotted lines. Based on this analysis, the distal long arm of chromosome 4 (arrow) is over-represented in the patient. The X and Y ratios reflect the fact that DNA from a female patient was compared with a male reference DNA. The ratio data of regions that contain mainly repeat DNAs and may exhibit large copy-number polymorphisms are unreliable and, therefore, excluded from the analysis (horizontal gray bars). Hybridization signals in these regions are partially suppressed by Cot-1 DNA.

FISH has also proved valuable for determining replication order and timing of specific DNA sequences.[44] Replicated DNA segments consisting of two sister chromatids appear as doublet hybridization signals during interphase, whereas unreplicated chromosomal segments with one chromatid give only single hybridization dots (Figure 1f). Most sequences have a defined time zone of replication within the cell cycle and replicate in a fairly

synchronous manner. Asynchronous DNA replication, which generates one doublet and one singlet hybridization signal on homologous interphase chromosomes, defines regions containing imprinted genes[45] or repeat DNA families.[46]

The general usefulness of interphase mapping is greatly hampered by the three-dimensional organization of chromatin in the cell nucleus. The data become more difficult or even impossible to analyze when the distance between markers is larger than several megabases. Based on the observation that less condensed interphase chromatin provides greater DNA resolution than metaphase chromosomes, different strategies have been developed to push the limits of resolution of FISH further by artificially decondensing chromatin. Briefly, the cells are lysed with high salt and/or detergent and the chromatin is spread across the surface of a glass slide either by gravity (tilting the slide) or by mechanical spreading. This can cause complete detachment of the DNA loops from the nuclear matrix, producing highly elongated chromatin fibers.[46–48] The finest level of DNA resolution of the various fiber FISH protocols is 1–10 kb, thus closing the gap between (molecular) cytogenetic and molecular physical mapping techniques. Alternatively, high-molecular-weight DNA molecules in solution can be stretched on glass surfaces by molecular combing.[49–51]

8.1 Fiber Fluorescence In Situ Hybridization

The following protocol describes the preparation of DNA fibers from agarose-embedded cells.[48] This technique can be adapted in most laboratories, producing suitable targets for high-resolution mapping.

To improve retention of DNA fibers on slides, the slides are coated with poly-L-lysine as follows. Put slides through 0.2 M HCl, ddH_2O, and acetone for 30 s in each solution, then allow to air-dry at room temperature. Place the clean slides in 0.15% gelatin, 0.03% sodium azide solution for 5 min at room temperature, then rinse for 30 s with ddH_2O and air-dry at room temperature overnight. Use molecular biology grade gelatin and filter the solution to get rid of any gelatin not completely in solution.

Place slides in 0.02% poly-L-lysine for 10 min at room temperature, rinse for 30 s with ddH_2O and air-dry for 1 h. Then repeat poly-L-lysine incubation and ddH_2O rinse and dry overnight at room temperature. Slides stored at 4 °C can be kept for months before use.

Most cell types can be used to prepare blocks for fiber FISH. Most commonly used are fibroblasts or peripheral blood lymphocytes. Collect, wash, and resuspend cells in $1 \times$ PBS (see Appendix 1) to a concentration of 2×10^6 cells per 100 µL. Warm this cell suspension slightly at 37 °C. Have ready 1.9% low-melt agarose kept at 50 °C. Mix melted agarose and cell suspension 1 : 1 and pipette into molds (blocks 100 µL or less) and chill for 30 min at 4 °C. Final cell concentration in the blocks is 10^6 cells in 100 µL.

Incubate blocks in a solution of 2 mg mL^{-1} proteinase K, 0.5 M EDTA, pH 8.0, 1% *n*-lauroylsarcosine. Use at least 1 mL of this solution per 100-µL block. Incubate for 48–72 h at 50 °C (with gentle agitation, if possible).

Leaving the blocks in the proteinase K solution, chill them for 30 min at 4 °C to firm up the gel fragments, then transfer them into TE (10 mM Tris–HCl, pH 7.5, 1 mM EDTA) buffer (see Appendix 1), and wash for two days at room temperature, changing the TE several times over this time period. Blocks can be stored in 0.5 M EDTA at 4 °C for months. Dialyse blocks stored in EDTA with several changes of TE before using for fibers.

For fiber formation, place approximately 10 µL of block on one end of a poly-L-lysine coated slide. Pipette onto the block around 40 µL of ddH_2O. Preheat the microwave oven to get the rotating glass plate very hot, by running empty for 5 min. One at a time, place a slide, with agarose and ddH_2O as described above, into the microwave with the slide near the outer edge of the rotating plate, and microwave at full power for 20–40 s.

Using a plain glass slide, spread the melted gel down the slide. Be sure that the agarose is completely melted. The angle of pulling should be low (20° or so) and the plain slide should be pulled with mild pressure. Ideally, the fluid should boil a bit as it gets pulled down the slide and the slide should appear dry immediately after pulling, i.e. extending the fibers. Allow slides to dry for about 1 h at room temperature.

Denature by placing the slides in a Coplin jar containing 70% formamide, $2 \times$ SSC at 74 °C for 4 min. This step is likely to remove quite a bit of the agarose. Put through an ethanol series (70%, 90%, 100%) at −20 °C and then allow to air-dry. As soon as the slides are dry, they are ready for probe application and hybridization. Make the fibers the same day as the hybridization will be done.

Following probe hybridization for 1–3 days, wash slides for 3×5 min at 42 °C in 50% formamide, $2 \times$ SSC and then 2×5 min at 42 °C in $0.5 \times$ SSC. Immunocytochemical detection should be performed according to standard procedures.

The distance for fiber FISH mapping is 5–500 kb. Cosmids of 30–40 kb length produce a string of fluorescent signals up to several dozen micrometers long. YAC probes produce very elongated straight signals on a certain percentage of fibers. The longer the hybridized YAC, the more likely it is that its sequence may be disrupted during fiber preparation. It is important to note

Figure 5 High-resolution FISH on extended chromatin fibers. (a) Hybridization of a green cosmid and a red PAC, which are closely adjacent but nonoverlapping. (b) Two partially overlapping PACs. (c) The red cosmid is partially overlapping the green PAC. The second red cosmid signal on the right-hand side is located at a distance of 20–30 kb and delineates a gene duplication. (d) The nonoverlapping PAC on the left-hand side is labeled simultaneously in green and red. The green cosmid on the right-hand side is partially overlapping with the red PAC. Scale bar, 10 μm.

that the fibers onto which clones are mapped are condensed to varying degrees and, therefore, a larger number of fibers (at least 20) should be analyzed for quantitative measurements.

Fiber FISH techniques can be used to map clones, i.e. cDNAs or cosmids, with a few kilobases resolution on individual straightened DNA molecules. It allows one to order probes relative to each other, to orient probes within a contig, and to determine the degree of overlap or gap size between different probes (Figure 5).

8.2 Molecular Combing

Molecular combing is a process in which a solution of DNA target molecules is placed in parallel orientation on a flat glass surface. In the most simple method, a drop of DNA solution is placed on a silanized coverslip and covered with another untreated coverslip, forcing the drop to spread. DNA molecules bind to the vinyl end groups ($-CH{=}CH_2$) of the silanized glass surface by their extremities only, presumably because of the

presence of a free protonated phosphate at the 5′-end of DNA molecules. The receding meniscus of the air–water interface during evaporation of the solution exerts a force on the DNA, resulting in a more or less uniform extension of the attached DNA molecules.[49,50] The highest density of linearized DNA molecules and constant stretching are achieved by using a DNA combing apparatus (Adil Instruments).[51] Silanized coverslips are dipped into a Teflon® reservoir with buffered DNA solution, resulting in random binding of the DNA molecules at one end (usually the 5′-end) or occasionally at both ends to the glass surface. When the slide is pulled out of the DNA solution by a mechanical device, the hydrodynamic action of the receding meniscus straightens the DNA molecules. Due to the silanized surface, the DNA molecules dry immediately as the coverslip comes out of the solution, permanently fixing them to the coverslip surface. A major advantage of molecular combing is that DNA molecules are aligned in a single direction and homogeneously stretched (approximately 2 kb μm^{-1}). Similarly to fiber FISH, most combed molecules are longer than several hundred kilobases and occasionally as long as 1 Mb.

Standard agarose blocks (see section 8.1) containing YAC DNA or total human genomic DNA are used for the preparation of DNA solution. The blocks will contain approximately 10^7 yeast cells, equivalent to 1 μg yeast DNA, or 10^6 diploid human cells, equivalent to 6.6 μg human genomic DNA, per 100 μL.

If blocks have been stored in 0.5 M EDTA, wash them in 15 mL TE (see Appendix 1) for at least 2 h. Stain each block with the fluorescent dye YOYO-1 (0.33 nmol μg^{-1} DNA) in 100 μL of 40 mM Tris–HCl, pH 8.0, 2 mM EDTA in 2-mL Eppendorf tubes for 1 h, protecting from light. YOYO-1 staining is optional. It allows visualization of combed DNA molecules on the glass surfaces, to judge the quality of preparations before hybridization.

Discard staining solution, add 500 μL TE and incubate for 20 min at 68 °C, then add 6 μL of 10 × NEB buffer (100 mM Bis Tris–HCl, pH 6.5, 10 mM EDTA, supplied with the enzyme) and 2 U of β-agarase and incubate for at least 2 h at 40 °C.

Dilute DNA with 0.5 M MES (morpholinoethanesulfonic acid) buffer, pH 5.5, very carefully in 15-mL round-bottom tubes. The final concentration of yeast DNA should be 0.25 μg mL^{-1} in 50 mM MES and of human genomic DNA 1.5 μg mL^{-1} in 150 mM MES. For human genomic DNA incubate for 30 min at 75 °C to assist re-suspension of the DNA.

Cool DNA solution to room temperature and pour into the Teflon® reservoir of the molecular combing apparatus. This solution can be stored at 4 °C for several weeks.

The molecular combing apparatus[51] consists of a vertically moving clip holding up to three coverslips. Silanized coverslips are dipped vertically into the Teflon® reservoir containing DNA solution and after 5 min of incubation are pulled out at a constant speed of 300 μm s^{-1}. During incubation DNA molecules in solution bind to the coverslip surface by their extremities. When the coverslips are pulled out of the DNA solution, the fixed horizontal meniscus (air–solution–coverslip interface) exerts a localized, constant, downward vertical force on the immersed part of attached DNA molecules, resulting in the DNA unwinding and straightening. The hydrophobic silanized glass surface dries immediately as it is pulled out of solution. The stretched, parallel DNA molecules are irreversibly fixed on the dry glass surface. Using a cyanoacrylate glue, mount coverslips on glass slides and dry slides overnight at 60 °C. Either use immediately for FISH or store in a desiccating box at −20 °C. Using this protocol, up to hundreds of human genomes or thousands of YAC molecules can be combed on a single coverslip, which allows accurate DNA mapping of probes on a single slide.

9 IMPORTANT APPLICATIONS

FISH is a very straightforward and powerful physical mapping technique which plays an increasingly important role in the study of genome structure and functional organization. Compared with other molecular mapping procedures, i.e. long- and short-range restriction analysis and PCR, the major advantage of FISH is the direct visualization of a sequence of interest on the homologous chromosome region and/or with respect to already mapped loci. FISH mapping on metaphase chromosomes allows the rapid localization of cloned DNA sequences to a specific chromosome region at a resolution of 1–3 Mb. FISH on interphase nuclei, extended chromatin fibers, and combed DNA molecules allows the ordering of probes, definition of the size of gaps and overlaps between clones, and the construction of contigs with much higher resolutions between 1 kb and 100 kb (Figure 5).[47–52] Metaphase and high-resolution FISH mapping have found widespread application in positional cloning projects, i.e. for the cytogenetic and molecular characterization of chromosome breakpoints (Figure 1c, d; Figure 2b, c). They greatly facilitate the construction of sequence-ready maps of well-ordered cosmid and PAC clones, which is crucial for the human genome project.

FISH has also added a new dimension to the cytogenetic analysis of structural and numerical chromosomal aberrations. It has become the most important adjunct technique to classical chromosome banding analysis, which is routinely being applied in prenatal and postnatal diagnostics and cancer cytogenetics. Because of

its higher sensitivity, specificity, and DNA resolution, FISH can detect cytogenetically cryptic chromosome rearrangements that could not be determined previously by conventional banding methods alone. For example, microdeletions and translocations involving the chromosome ends (Figure 1a, b) appear to be an important cause of disease in patients with unexplained mental retardation[53] and most likely also in other patient populations. Similarly, patients with seemingly balanced chromosome rearrangements and a recognizable clinical phenotype may show deletions of several megabases of DNA in the breakpoint region(s).[13] Cytogenetically and genetically anchored large-insert clones for any chromosome region of interest are available for routine cytogenetics and can be adapted with unlimited flexibility to the study of cytogenetically cryptic and visible chromosome abnormalities.

Chromosome-specific DNA libraries are particularly useful to paint chromosomes involved in structural or numerical aberrations in both metaphase and interphase cells and to identify the chromosomal origin of marker chromosomes. Recent advances in combinatorial probe labeling and multicolor FISH allow the simultaneous visualization of all 24 human chromosomes in different colors (Figure 3). This has wide utility in cancer cytogenetics for characterizing even extensively rearranged chromosomes and karyotypes that produce very complex banding patterns[35,36,38] In addition, CGH approaches allow one to rapidly screen tumor and patient genomes for complete and partial chromosome gains and losses and for gene amplifications (Figure 4).[18,39]

FISH has the added advantage over chromosome banding that it also detects chromosomal abnormalities, especially numerical aberrations, in interphase nuclei (Figure 1e, g). Chromosome-specific α-satellites produce very intense and discrete hybridization signals on interphase nuclei and, therefore, are frequently used to measure aneuploidy rates for individual chromosomes in tumors,[54] sperm,[55] pre-implantation embryos,[56] and other cell substrates, where metaphase chromosome preparation is difficult or even impossible. To a lesser extent, region-specific large-insert clones may also be used. Given the large contribution of chromosomes 13, 18, 21, X, and Y to constitutional chromosomal aneuploidies, interphase assays determining copy-numbers of these chromosomes have become an important complementary tool in pre-implantation and prenatal diagnostics.[57] Specific probes spanning or binding near chromosomal breakpoints, i.e. of the Philadelphia chromosome in chronic myelocytic leukemia, allow the interphase analysis of translocations and other structural rearrangements.[58]

In addition to physical mapping and diagnostic applications, FISH has proven tremendously useful for the study of genome evolution (Figure 2). Comparative mapping of individual gene loci has allowed the generation of homology maps in at least some important animal models.[59,60] More direct approaches to comparative genome mapping involve the delineation of contiguous conserved (syntenic) segments containing hundreds of homologous loci by Zoo-FISH using human (or mouse) DNA libraries on chromosomes of heterologous species.[61–63] The presence of orthologous genes on interspecific homologous chromosome segments (conservation of synteny) reflects the common phylogenetic origin of species and also the ancestral genomic organization. Comparative (chromosome homology) maps can be used to predict the locations of homologous genes in the human and animal genomes and to answer important questions about the forces guiding mammalian genome organization, evolution, and pathology. They will also be instrumental for integrating the genetic, cytogenetic, and molecular information in human and animal species that is accumulating through genome research.

APPENDIX 1

Buffers and Stock Solutions

Antifade Mounting Solution

DABCO	2.33 g	(2.3%)
Tris–HCl (1 M) (pH 8.0)	2 mL	(20 mM)
Glycerol	90 mL	(90%)
Distilled water	to 100 mL	

Store at −20 °C in dark vials. Solution can be used for up to 6 months.

Blocking Solution

20 × SSC	20 mL	(4 × SSC)
BSA (inexpensive grade)	3 g	(3%)
Tween 20 (10%)	1 mL	(0.1%)
Distilled water	to 100 mL	

Stir for at least 10 min to completely dissolve the BSA. Always prepare freshly.

Bovine Serum Albumin (10%)

BSA (fraction V) (molecular biology grade)	1 g	(10%)
Distilled water	to 10 mL	

Dissolve in distilled water and sterilize by filtration. Store at −20 °C in aliquots.

Denaturation Solution

Formamide (deionized)	1.4 mL	(70%)
20 × SSC (pH 7.0)	0.2 mL	(2 × SSC)
Distilled water	0.4 mL	

Always prepare freshly.

Detection Buffer (for the Dilution of Streptavidin and Antibodies)

20 × SSC	200 µL	(4 × SSC)
BSA (10%)	100 µL	(1%)
Tween 20 (10%)	10 µL	(0.1%)
Distilled water	to 1 mL	

Dextran Sulfate (50%)

Dextran sulfate	50 g	(50%)
Distilled water	to 100 mL	

Dissolve in distilled water, autoclave, and store at −20 °C.

Disodium Ethylenediamine Tetraacetate (0.5 M) (pH 8.0)

EDTA · $2H_2O$	186.1 g	(0.5 M)
NaOH pellets	~20 g	
Distilled water	to 1 L	

Adjust the pH by addition of NaOH to approximately 8.0. Stir vigorously until the EDTA goes into solution.

Formamide (Deionized)

Formamide (molecular biology grade)	100 mL
Mixed-bed ion-exchange resin (i.e. Bio-Rad AG 501-X8)	10 g

Stir for at least 30 min and filter twice to remove the resin. The conductivity of deionized formamide should be >100 µS. Store in small aliquots at −20 °C.

Hybridization Mixture (2×)

20 × SSC	2 mL	(4 × SSC)
Dextran sulfate (50%)	4 mL	(20%)
Distilled water	4 mL	

Mix vigorously and store in small aliquots at −20 °C.

Magnesium Chloride (1 M)

$MgCl_2 \cdot 6H_2O$	203.3 g	(1 M)
Distilled water	to 1 L	

$MgCl_2$ is extremely hygroscopic. Do not store opened bottles for a long time.

β-Mercaptoethanol (0.1 M)

BME (14.4 M)	70 µL	(0.1 M)
Distilled water	to 10 mL	

Store in small aliquots in the dark at −20 °C.

Nick Translation Buffer (10×)

Tris–HCl (1 M) (pH 8.0)	5 mL	(0.5 M)
$MgCl_2$ (1 M)	0.5 mL	(50 mM)
BSA (10%)	50 µL	(0.5 mg mL^{-1})
Distilled water	to 10 mL	

Phosphate-buffered Saline (10 × PBS)

Sodium chloride (NaCl)	79.5 g	(1360 mM)
Potassium chloride (KCl)	1.5 g	(20 mM)
Sodium phosphate, dibasic (Na_2HPO_4)	15 g	(106 mM)
Potassium phosphate, monobasic (KH_2PO_4)	2 g	(15 mM)
Distilled water	to 1 L	

Adjust pH to 7.2–7.4 and autoclave.

Phosphate-buffered Saline (1×) (pH 7.3)

PBS (10×)	100 mL
Distilled water	900 mL

Postdetection Wash Solution

20 × SSC	100 mL	(4 × SSC)
Tween 20 (10%)	5 mL	(0.1%)
Distilled water	to 500 mL	

Posthybridization Wash Solution

Formamide (does not have to be deionized)	50 mL	(50%)
20 × SSC	10 mL	(2 × SSC)
Distilled water	to 100 mL	

RNase (100 mg mL^{-1})

RNase A (powder)	1 g	(100 mg mL^{-1})
NaAcetate ($C_2H_3O_2Na \cdot 3H_2O$) (3 M)	33 µL	(10 mM)
Distilled water	to 10 mL	

Boil for 10 min to inactivate contaminating DNase activity and store in small aliquots at −20 °C.

Saline Sodium Citrate (20 × SSC) (pH 7.0)

Sodium chloride (NaCl)	175.3 g	(3 M)
Sodium citrate ($Na_3C_6H_5O_7 \cdot 2H_2O$)	88.2 g	(0.3 M)

Adjust pH to 7.0 with a few drops of 10 M NaOH and sterilize by autoclaving.

Salmon Sperm DNA

Salmon sperm	1 g	(10 mg mL^{-1})
Distilled water	100 ml	

Dissolve salmon sperm DNA in distilled water, keep in boiling water for ~30 min so that the size range is between 100 and 500 bp, and store at −20 °C.

Sodium Acetate (3 M) (pH 5.2)

NaAcetate ($C_2H_3O_2Na \cdot 3H_2O$)	408.3 g	(3 M)
Distilled water	to 1 L	(~800 mL)

Adjust pH with glacial acetic acid to 5.2 and adjust volume to 1 L.

Sodium Dodecyl Sulfate (10%)

SDS	100 g	(10%)
Distilled water	to 1 L	(~900 mL)

Wear a mask when weighing SDS. Heat to 68 °C to facilitate dissolution of the SDS and adjust pH to 7.2 with HCl.

Taq *Polymerase Buffer (10×) (without $MgCl_2$)*

Tris–HCl (1 M) (pH 9.0)	1 mL	(100 mM)
KCl (1 M) (74.55 g L^{-1})	5 mL	(500 mM)
Triton X-100	100 µL	(1%)
Distilled water	to 10 mL	

Buffer is usually supplied with the enzyme.

TE

Tris–HCl (1 M) (pH 7.4)	1 mL	(10 mM)
EDTA (0.5 M)	0.2 mL	(1 mM)
Distilled water	to 100 mL	

Tris–HCl Buffer (1 M) (pH 7.4)

Tris base	121.1 g
Hydrochloric acid (HCl conc.)	~70 mL

Distilled water	to 1 L

Cool; adjust to pH 7.4 and add distilled water to 1 L; autoclave.

Tris–HCl (1 M) (pH 8.0)

Tris base	121.1 g
Hydrochloric acid (HCl conc.)	~42 mL
Distilled water	to 1 L

Tween 20 (10%)

Tween 20	10 mL	(10%)
Distilled water	90 mL	

Stir for at least 10 min to completely dissolve the Tween 20 and store at 4 °C.

A physical map of a region or the entirety of the genome of an organism is a representation of the genome providing information on the relative order and the arrangement of physically defined entities. For most physical maps, these entities are cloned genomic DNA fragments propagated in cosmids, bacteriophage P1, bacterial artificial chromosomes (BACs), P1-derived artificial chromosomes (PACs), or yeast artificial chromosomes (YACs). The various cloning systems differ in the sizes of the cloned DNA fragments and the fidelity of DNA structure maintenance. Owing to its excellent properties, the BAC system is the premier system for this purpose. Several different, highly efficient procedures have been developed and applied successfully to identify overlaps between the DNA fragments represented in different clones. The procedures are based on different experimental techniques, including nucleic acid hybridization, DNA amplification through polymerase chain reaction (PCR), DNA restriction fragment analysis, and DNA sequencing. Applied separately or in combination, these procedures have been used successfully to generate extensive physical maps of human, animal, and plant genomes.

1 INTRODUCTION

Physical mapping refers to an experimental approach devoted to the establishment of a representation of the genome (the total complement of genetic information, represented by the cellular DNA) of a particular organism. The representation thus created is called a physical map. This map of the genome, which must not be mixed up with a genetic map (see below), is based on physically defined entities such as DNA restriction fragments or cloned DNA fragments. It provides information on the relative order and arrangement of these entities. Partial or complete physical maps may be constructed on the basis of DNA restriction fragment patterns or through in situ hybridization of isolated (cloned) DNA fragments to chromosomes. Most physical maps of genomes hitherto assembled, however, are based on cloned fragments of genomic DNA maintained in clones of genomic libraries (e.g. cosmid, YAC, or BAC libraries; see sections 2.1–2.3). The fully elucidated genomic DNA sequence currently available for yeast and several prokaryotic microorganisms may be regarded as the ultimate physical map. The quality of clone-based physical maps, which essentially cover the information about which clones contain overlapping genomic DNA fragments, is very strongly influenced by the properties of the cloning system used to propagate the DNA fragments. Thus, DNA cloning systems, which provide the highest degrees of maintenance of the original arrangements of the DNA molecules as they are present in the DNA of the organism under investigation and provide the highest degree of stability during propagation, are most suitable for these purposes. Owing to their specific properties, BACs are the premier system currently available for cloning and maintenance of large genomic DNA.

In contrast to a physical map, the genetic map of the genome of an organism is a rather imaginary map, which is based on the frequencies of recombination (crossing over) events occurring between genetic loci. These loci are defined either as mutations in genes that are identified through alterations in the properties of the organism (phenotypic changes) or as polymorphic DNA fragments, the sequence differences of which can be monitored directly or indirectly.

The establishment of a physical map of a genome is an intrinsic part of a detailed genome analysis. In particular, when linked to the genetic map, a high-resolution physical map is of high value for studies

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

devoted to genome organization and function, including the elucidation of the relations of physical to genetic distances and for the coordination and performance of sequencing projects. Its immediate value to the research community, however, may be even higher through the strong support it provides to map-based gene-cloning efforts. Through this procedure, genes could be isolated and studied at the molecular level that are only characterized by a corresponding mutant phenotype (alteration in morphological, developmental, metabolic, or behavioral properties of an organism caused by the genetic change). The availability of this procedure thus provides a means to gain entirely novel information on the molecular mechanisms underlying the multitude of processes occurring in living organisms.

2 DNA CLONING SYSTEMS APPLICABLE TO PHYSICAL MAPPING EXPERIMENTS

To be useful for the application of physical mapping procedures, a DNA cloning system has to meet several requirements. Higher eukaryotic organisms usually have genomes of enormous sizes, which may range from ca. 97 Mbp as in the case of the nematode *Caenorhabditis elegans*,[1] 130 Mbp in the case of the plant *Arabidopsis thaliana*,[2] ca. 165 Mbp in the case of the fruit fly *Drosophila melanogaster*,[3] ca. 430 Mbp for rice (*Oryza sativa*[4]), ca. 3 Gbp in the case of man (*Homo sapiens*[5]) and corn (*Zea mays*[6]), and up to 16 Gbp for wheat (*Triticum aestivum*[6]). Of major importance, therefore, is the size of DNA fragments, which can be cloned and stably maintained in a particular cloning system. The size of the DNA fragments determines the number of clones to be handled in order to represent (nearly) the entire genome. To provide sufficient coverage of the genome, a genomic library of a minimum of 10-fold genome representation (number of clones in the library × average insert size/genome size) should be used for a physical mapping project.[7] This extensive coverage is required to ensure a very high probability of representation of every region in the genome and to provide sufficient overlap between the individual clones to be detectable by the mapping procedure. Thus, in the case of a 100-Mbp genome, a library of ca. 100 000 clones would be necessary in the case of an average insert size of 10 kbp, a library of ca. 10 000 clones would be necessary in the case of an average insert size of 100 kbp, and a library of ca. 1000 clones would be sufficient in the case of an average insert size of 1000 kbp (= 1 Mbp). The number of clones would influence not only the effort required for ordered handling, but also the number of experiments to be performed for ordering them (see below). Although clone libraries with very large insert sizes are advantageous in terms of reducing the amount of labor for handling and processing, they are disadvantageous, on the other hand, in terms of the resolution achieved. Since robotic devices have been developed, which allow the handling of very large numbers of clones (in the range of 100 000),[8] the balance between the number of clones to be handled/number of experiments to be done and the resolution achieved may be shifted more and more toward the latter. A second important criterion is the quality of the DNA represented in the clones of the library. Various DNA cloning systems differ strongly in the fraction of aberrant clones, which may be chimeric (composed of DNA fragments derived from different, noncollinear regions of the genome that were fused upon cloning), may carry rearranged DNA fragments, or may have suffered from deletions. The latter two changes in the cloned DNA fragments may occur not only during the cloning procedure itself, but also during clone propagation. Finally, various cloning systems differ in their properties in terms of handling, including the requirements for culture and/or storage of the clones, or the procedures used for the isolation of the cloned DNA.

Several different DNA cloning systems are available; the major properties and advantages/disadvantages will be mentioned briefly in the following sections before the preferred BAC system is described in more detail.

2.1 Cosmids

Cosmids are vector systems for propagation of DNA fragments in the bacterial host *Escherichia coli*.[9] Owing to the specific cloning procedure, which involves packaging of the DNA molecules into bacteriophage λ particles, the size of inserted DNA fragments is limited to a maximum of ca. 50 kbp. Various different cosmid vectors are available, which may differ in the stability of the cloned DNA fragments. Routine procedures are available for the generation, handling and storage of cosmids.[9]

2.2 Bacteriophage P1

The bacteriophage P1-based DNA cloning system also relies on the bacterial host *E. coli* for propagation.[10] In analogy to the cosmid system, DNA molecules are packaged into phage P1 particles for delivery into the *E. coli* cells. Advantageous in comparison to the cosmids is the increased size of the packaged DNA molecules, which allows a maximum insert size of ca. 100 kbp. Although a variety of P1 libraries have been established in various laboratories, the P1 cloning procedure cannot be regarded generally as a routine.

2.3 Yeast Artificial Chromosomes

YACs are propagated in the bakers' yeast *Saccharomyces cerevisiae*[11,12] as linear molecules (chromosomes) equipped with centromeric and telomeric sequences, elements required for initiation of replication, and selectable marker genes. A variety of YAC libraries have been established for animals,[13–17] plants,[18–26] and humans,[27–30] which proved the suitability of the YAC system to clone very large DNA fragments (above 1 Mbp) and which displayed average insert sizes ranging from ca. 100 kbp up to 800 kbp. Although YACs are superior to all other DNA cloning systems in terms of the size of the inserted DNA fragments, this cloning system suffers from two major disadvantages. In many YAC libraries, very large fractions of clones (up to 40 or 50%) carry aberrant, nonauthentic DNA fragments (showing chimerism, rearrangements, deletions, and/or instability[31–33]). A very high proportion of the results obtained on YAC clones during the course of a physical mapping project may thus be erroneous and may require the investment of additional very strong efforts for their identification and elimination. The fraction of aberrant clones may, however, be reduced through the use of optimized yeast strains.[34–36] Other limitations of this system are the procedures for handling and processing of the clones, which in general are more laborious than for the *E. coli*-based systems. This is particularly true for the procedures to be applied for the isolation and purification of the cloned DNA fragments.[37]

2.4 Bacterial Artificial Chromosomes and P1-derived Artificial Chromosomes

2.4.1 Characteristics of the Systems

These two DNA cloning systems rely on the host system *E. coli*, which thus provides the opportunity to apply (almost) all routine procedures for clone propagation, handling, and storage that are usually established in molecular biologically oriented laboratories.[9] The BAC system[38] has been developed on the basis of an F-plasmid-derived replicon, which includes the factors that control the number of plasmid copies per bacterial cell to be 1–2. This system has been demonstrated to be capable of taking up and stably maintaining large DNA fragments (up to a size of ca. 350 kbp).[38] Apparently, the strict copy number control exerted by this system is the key to the highly faithful representation of the genomic DNA molecules and their very stable propagation. The developed BAC vectors, such as pBAC108L,[38] pBeloBAC11,[39] pECBAC1,[40] or pBeloBAC-Kan[41] (see Figure 1), display a variety of favorable features. These include multiple cloning sites flanked by recognition sites for rare cutting restriction enzymes (useful for the excision of the cloned DNA fragments), a lacZ-based reporter system to monitor recombinant clones, and the presence of bacteriophage T7 and Sp6 promoters flanking the cloning site (useful for the generation of labeled end-probes; see below). Specific BAC vector variants such as pBiBAC[42] or pTAC[43] have been created, which allow their use in *Agrobacterium tumefaciens*-mediated transfer of the inserted DNA into plants. This opens the attractive opportunity to transfer cloned large DNA fragments into plants, providing the means to identify rapidly novel genes or to identify and transfer quantitative trait loci. The PAC vector[44] resembles the BAC vector, but

Figure 1 Schematic representation of the pBeloBAC-Kan vector. Indicated are the functional elements involved in replication and copy number control (oriS, repE, parA, parB), the selectable marker (Kanamycin resistance), and details of the multiple cloning site. The latter is flanked by the phage T7 and SP6 promoters suitable for the generation of labeled end-probes and is located within the lacZ gene that allows blue/white selection for recombinant clones. The cloning site is furthermore flanked by recognition sites for rare cutting restriction enzymes, and loxP and cosN sites are present, which may be used for the high-specificity cleavage.

is based on the P1 replicon and carries a marker for the selection for recombinant clones (sacB). In contrast to the aforementioned P1 cloning system (section 2.2), PACs, like BACs, are introduced into the *E. coli* host cells by electroporation. The sizes of the recombinant BAC or PAC molecules are therefore not limited by the capacity of phage particles for DNA uptake.

Several BAC and PAC libraries have been established recently for plants,[41,45–49] animals,[50–53] and humans,[39,44,51] with average insert sizes ranging from ca. 100 kbp up to 235 kbp. These libraries provide deep genomic coverages and easy access to high-quality genomic DNA suitable for manipulation, such as sequencing, exon trapping, complementary DNA selection, microsatellite marker isolation, and fluorescence in situ hybridization studies.[38,54–57]

2.4.2 Generation of a BAC Library

For the generation of a BAC library, several experimental steps are necessary (see Figure 2; for a detailed description of the BAC cloning procedure, see Shizuya et al.[38] and Mozo et al.[41]):

Figure 2 BAC cloning procedure applied for the generation of an *Arabidopsis thaliana* BAC library. In this case, protoplasts prepared from root-derived suspension cultures were used as a source of high-molecular-weight DNA prepared through proteinase K digestion after embedding in agarose. The high-molecular-weight DNA was partially digested by *Eco*RI restriction enzyme/methylase competition, fractionated by preparative pulsed-field gel electrophoresis (PFGE), concentrated and ligated into the pBeloBAC-Kan vector. Ligation products were transfected into *E. coli* by electroporation and white colonies grown in the presence of X-Gal/IPTG (substrate and inducer of the lacZ gene) were picked and stored at −70 °C in microtiter dishes.

1. High-quality high-molecular-weight DNA (≥1 Mbp) has to be prepared from the source organism. This may be achieved by agarose embedding of cells or protoplasts (plant cells without cell wall) or nuclei and liberation of the DNA by a proteinase digestion.
2. This DNA has to be partially digested with a suitable restriction enzyme (such as *Bam*HI, *Sau*3A, *Hin*dIII, *Eco*RI) to yield DNA fragments in the desired size range (150–250 kbp). The limited digestion can be achieved by limited incubation time, suboptimal (e.g. low temperature) incubation conditions, or by a competition reaction of restriction enzyme and a corresponding methylase.[58] The last possibility has the advantage over the first two of allowing the reaction to be run to completion, which is of relevance if the available high-molecular-weight DNA concentration is low.
3. The DNA fragments of the desired size range have to be separated from the molecules of smaller size that inevitably also occur and would be preferentially cloned subsequently. PFGE[59] is used to separate the large DNA molecules. Usually, at least two successive rounds of PFGE under different conditions are necessary to achieve sufficient purification. In the case of low DNA concentrations, a subsequent step for DNA concentration may be necessary/desirable through another electrophoresis involving an agarose gel of higher concentration.[60]
4. The insert DNA fragments thus generated are released from the agarose matrix by enzymatic digestion of the agarose and the liberated DNA molecules are ligated to dephosphorylated pBAC vector DNA.
5. The ligation products are transferred into *E.coli* cells by electroporation under optimized conditions[61] that are favorable for the uptake of large molecules. Depending on the BAC or PAC vector used, recombinant clones may be recognized through the expression of scorable (e.g. lacZ) or selectable marker systems (e.g. sacB). Recombinant clones are picked into liquid culture medium (preferably in microtiter plates) and transferred to −70 °C for long-term storage. For propagation (e.g. library replication), establishment of colony filters for DNA hybridization experiments (see below), or BAC DNA preparations, standard *E. coli* handling procedures can be applied.[9] To verify the presence of high-quality recombinant clones, a set of randomly selected clones should be tested for insert sizes by BAC DNA isolation, digestion with an appropriate rare cutting restriction enzyme (e.g. *Not*I) and PFGE.

3 APPROACHES TO PHYSICAL MAPPING

Various techniques are available for identification of overlapping clones, which essentially is the information to be gathered during a physical mapping program. To this end, experiments are designed to group efficiently as many clones as possible into contigs (contiguous sequences). Several procedures have been developed that rely on different types of information to detect the presence of common DNA regions in different clones.

3.1 Hybridization-based Procedures

The property of DNA molecules to be composed of two complementary strands is used in hybridization experiments. Thus, DNA molecules can be identified through hybridization to carry identical or highly similar sequences. Screening of a clone library by hybridization is usually done after fixation of DNA liberated from the clones to a solid support, e.g. a nylon membrane (see Figure 3). The immobilized DNA is then incubated with a labeled probe (a certain species of radioactively, fluorescently, or digoxygenin-labeled DNA molecules) under appropriate conditions.[9] Through the detection of the label at specific positions of the filter, the identity of the corresponding (overlapping) clone can be determined. It is particularly advantageous when applying such a procedure to use gridded libraries, the clones of which are fixed to defined positions on the filter.[8] In this case, large numbers of hybridizations can be performed efficiently and the results of the hybridizations can be evaluated rapidly.[62] This approach has gained strong support by the development of robotic devices, which provide the means to fix at high precision very large numbers of clones at high density to membranes that can be produced in large quantities.[8] The labeled probes used may be derived from individual selected clones (''chromosome walking''[63]), they may be oligonucleotides (''hybridization fingerprinting''[64,65]), or they may be genetically mapped markers (''anchoring''[66]). Relatively short stretches of sequence identity are sufficient to detect overlaps by hybridization, which is thus useful also for genomic regions of sparse coverage in the libraries used.

The information gathered by hybridization, however, does not provide any indication of the degree of overlap between clones. Such information may be obtained, for example, by application of the DNA fingerprinting technique (see section 3.3). Erroneous hybridization results may be generated through the appearance of highly related DNA sequences present at different regions in the genome. The specific properties of the genome investigated therefore strongly influence the viability of a hybridization-based mapping approach. Because all

Figure 3 Physical mapping through hybridization. To identify overlap between clones of an ordered large insert library, labeled DNA probes (e.g. derived from clones of the library) are hybridized to the DNAs of the clones fixed to a solid support (e.g. a nylon membrane). The procedure is most efficiently performed in an iterative manner (‘‘sampling without replacement’’) by preparing new labeled probes only from clones that have not been hit by any previous hybridization. Established contigs eventually merge through clones hit by more than one probe. Here, D14 is a connecting clone; it is marked in green on the filter because it was identified by the probe derived from clone D22 (marked in blue) and by the probe derived from clone C22 (marked in yellow).

clones of the library are checked for overlap with the probe at the very same time, hybridization is intrinsically highly parallel and it has an extremely high throughput. In addition, it readily allows the integration of data generated by the application of different types of probes, such as clones from different libraries (e.g. cosmid, BAC, or YAC clones), total labeled clones or clone end-probes, or mapped markers. The use of the latter type of probe is highly desirable because it would result in an alignment of the physical map with the genetic map.[67]

An efficient procedure for the generation of contigs (physical mapping) through iterative hybridization has been developed and applied successfully to generate high-resolution cosmid and P1 maps of *Schizosaccharomyces pombe*.[7] The strategy of ''sampling without replacement'' (see Figure 3) was applied here, which involves the selection of clones to be labeled and hybridized to the complete genomic libraries from only the subset of clones never hit by any of the previous hybridizations. This procedure greatly reduces the number of hybridization reactions that have to be carried out in comparison to random probe selection. A modification of this procedure involves the generation of hybridization probes from both ends of the selected clones.[68] In addition to generating larger contigs than through the use of single end-probes, the double end-probe procedure provides information on the relative orientation of the identified clones. The latter approach recently was applied successfully to the generation of the first BAC-based physical map[89,70] (see section 4).

The efficiency of the ''sampling without replacement'' procedure is limited by the frequency of repetitive sequences present in the cloned DNA fragments, which may comprise very substantial fractions of large eukaryotic genomes. The presence of such repetitive sequences within the labeled probes would cause the generation of noninformative results. In this situation it is advisable to use oligonucleotides as probes or to select DNA probes from sources enriched for single/low-copy sequences such as complementary DNAs, identified as expressed sequence tags (ESTs).

3.2 Methods Based on Polymerase Chain Reaction

Sequence-specific DNA amplification via PCR provides another efficient means to test recombinant clones for the presence of a particular piece of DNA. Thus, specific pairs of oligonucleotide primers designed according to the sequences of known stretches of DNA are applied in large sets of amplification reactions containing DNAs isolated from the various different clones of a genomic library as templates. Because DNA amplification to detectable levels would only occur in those reactions supplied with template DNA derived from clones carrying the cognate DNA region, PCR can be used as a very sensitive and reliable assay for the presence/absence of specific DNA sequences, even in complex mixtures. The DNA regions of known sequence have been termed ''sequence-tagged sites'' (STSs)[71] and the corresponding mapping procedure is known as ''STS content mapping''[72] (see Figure 4).

The major advantage of STS content mapping over the use of cloned DNA fragments, e.g. as hybridization probes, is the immediate access to any STS by any interested laboratory as soon as it is made known. An STS can be defined completely as information (essentially a short stretch of DNA sequence plus instruction for the PCR assay) that can easily be deposited in a database. No access to specific biological material such as a cloned DNA fragment, which initially might have led to the identification of an STS, is required to perform an STS assay. This ''common language'' provides an ideal basis for collaborative approaches between many geographically dispersed groups, as may frequently be the case for mapping projects devoted to the analysis of very large and complex genomes. A further advantage of STS content mapping is its applicability even to genomic regions rich in repetitive sequences, provided that these sequences are interspersed with single-copy sequences that can be used for primer design.

Disadvantages of STS content mapping include the requirement for quite large amounts of sequence information to be available prior to the initiation of a mapping project or to be produced during the conductance of the project. The PCR method itself bears the risk of producing false negative (lack of DNA amplification in cases where it should occur) and false positive results (DNA amplification in cases where it should not occur). These need to be identified through proper controls and may require additional efforts for the optimization of PCR conditions. Owing to the need for performance and evaluation of very many DNA amplification reactions (see below), this procedure is very labor- and cost-intensive.

STS content mapping usually involves the isolation of DNA from a specific subset or, for all clones, from an ordered large insert library, and subjecting these DNAs to individual STS assays that include PCR amplification and evaluation of the PCR products. Because the clone libraries usually consist of several tens of thousands of clones and several thousand STSs have to be tested for the construction of genome-wide maps,[73,74] several million STS assays may have to be performed. It is therefore almost inevitable that appropriate clone pooling strategies are used, which provide an efficient means to reduce the number of STS assays required but still allow the identification of individual positive clones (see Figure 4). To be able to process the enormous numbers of STS assays ($\geq$15 million

Figure 4 Physical mapping through application of PCR. After multidimensional pooling of clones of an ordered large insert clone library, DNA prepared from the clone pools is subjected to PCR using single-copy-sequence (STS)-specific oligonucleotide primers. Successful amplification highlights the presence of a clone within the positive pool that carries the particular DNA sequence. The information obtained on the various pools is deconvoluted to identify individual positive clones. In the case of STS 1 (marked red), a positive signal was detected in column pool 22 and row pool E of plate 1. The positive clone therefore is clone E 22 from plate 1 (1 E 22). Clone contigs are established according to the presence of common STSs; contigs eventually merge through clones hit by more than one STS.

Figure 5 Physical mapping through DNA fingerprinting. DNA isolated individually from all clones of an ordered large insert clone library is treated with a restriction endonuclease and the resulting DNA fragments are separated according to their size by gel electrophoresis. Overlap between clones is detected through the presence of common bands in the gel image, which correspond to common DNA fragments. Contigs are established according to the information about common DNA fragments (marked in red, green, and blue) carried by the clones.

have been performed during the construction of a human STS-based map,[73] and ≥17 million for establishing a map of the mouse genome[74]), large-scale automation systems are required. Analogous to the hybridization-based approaches, specific optimized procedures for selection of the STSs[68] may be applied to limit the number of necessary STS assays. Nonrandom selection of STSs was applied successfully for the generation of a physical map of the *Drosophila* euchromatic genome.[75] In addition to the aforementioned physical maps of entire genomes, a large number of YAC-, P1-, PAC-, or BAC-based maps for specific chromosomes or chromosomal regions have been established through involvement of STS content mapping.[76–83]

3.3 DNA Fingerprint Analysis

The property of DNA restriction enzymes to cleave DNA molecules at specific recognition sequences provides the basis for another type of procedure for the recognition of the presence of common (identical) DNA stretches: when digested with an appropriate restriction enzyme, DNA molecules are cleaved into a specific pattern of DNA fragments that form a characteristic pattern of bands when separated by gel electrophoresis and visualized (DNA fingerprint[84]). In the case of two clones sharing a common stretch of DNA, this would give rise to a number of common DNA fragments that can thus be used to detect overlaps (see Figure 5). The probability of detection of true overlaps by this procedure is determined by the number of common fragments and the size of the analyzed genome. This procedure has been applied successfully for mapping all or parts of the genomes of *Caenorhabditis elegans*,[84,85] yeast,[86,87] *E. coli*,[88] *Drosophila melanogaster*,[89] and humans.[30,90–92]

In comparison to hybridization, much more extended regions of sequence identity are required to provide a sufficient number of common DNA fragments for the exclusion of similarly sized DNA fragments appearing by chance. Therefore, a high redundancy of the clone libraries is an essential prerequisite and very many clones have to be fingerprinted to generate a complete physical map.[30] Furthermore, analytical systems that permit precise and reproducible DNA fragment sizing and data acquisition in a high-throughput fashion are necessary. Automated methods are therefore required to pursue this approach, which has been further developed to be applicable to very-high-throughput analysis.[93] In contrast to hybridization, however, DNA fingerprinting is less prone to producing erroneous results caused by the appearance of highly related DNA sequences present at different regions in the genome. Furthermore, the results of a DNA fingerprint analysis provide information on the extent of overlap of clones derived from the number and the sizes of common DNA fragments. This information is of particular relevance for the selection of a minimal set of clones spanning a certain region, e.g. for sequencing.

3.4 Clone (End-) Sequencing (Sequence-tagged Connector Approach)

As a fourth type of approach and a complement to the DNA fingerprinting approach, Venter et al.[94] proposed a procedure for mapping clones primarily based on sequence analysis, which has come within reach through the enormous increases in DNA sequencing capacity. The principle underlying this approach is the identification of overlap between clones directly through the identification of a common DNA sequence (see Figure 6). To this end, a large collection of BAC clones, such as a BAC library representing an average 15-fold genome representation, is analyzed by sequencing both ends of the inserted DNA fragments and a corresponding end-sequence database is established. Starting with a ''seed-BAC'' that is completely sequenced, all overlapping BACs are recognized through a stretch of common DNA identified upon search of the end-sequence database. This approach is cost effective, especially for very large genome sequence analysis projects, and has proven to be highly viable, e.g. for the *Arabidopsis thaliana* sequencing project (S. Rounsley, personal communication). Because it relies rather exclusively on sequence analysis and the physical map is actually developed through the complete genomic sequencing, it is only applicable to mapping genomes that are intended to be fully sequenced.

4 BAC-BASED PHYSICAL MAPPING OF THE *ARABIDOPSIS THALIANA* GENOME

Arabidopsis is a small flowering plant that today serves as the major model system in plant molecular genetics[95] and that has been chosen as the subject of the first large-scale project intended to determine the full genome sequence of a plant.[96] This sequencing project, together with the increasing interest in map-based gene cloning, has highlighted the requirement for a complete and accurate physical map of this plant species. Two complementary approaches have been initiated to achieve this goal.[69,97] The final merging of the data produced by these two approaches recently led to the establishment of the first reported map of a complex organism based entirely on BAC clones. This map represents the most homogeneous and complete physical map established to date for any plant genome.[70]

In the first of the two approaches, the aforementioned ''sampling without replacement'' procedure of high-throughput hybridizations of BAC end-probes was

Figure 6 Physical mapping through DNA sequencing. The DNA sequences located at the ends of the cloned DNA fragments of every clone of an ordered large insert clone library are determined and deposited in a database. Thereafter, an individual clone (“seed clone”) is selected for complete sequencing. This sequence information is used to search the end sequence database for sequence identities. Matches between the sequence of the “seed clone” and end sequences of other clones demonstrate the presence of common DNA regions within the cloned DNA fragment of the various clones and provide the means to determine precisely the degrees of overlap. Clones with minimal overlap to the “seed clone” are selected for sequencing of the entire inserted DNA fragment and the elucidated sequence is used again to query the end sequence database. Through this procedure, a clone-based physical map of a genome is established simultaneously with the determination of the entire genome sequence.

applied because it was shown to work efficiently for this organism.[69] The nuclear DNA of *Arabidopsis thaliana*, which is estimated to cover ca. 130 Mbp, is characterized by a low content of interspersed repetitive sequences.[98] It is therefore particularly well suited for the application of a hybridization-based physical mapping approach. When evaluated on the basis of 1000 end-probe hybridization experiments, the applied “double-end-probe sampling without replacement” approach was found to be highly efficient, with about 50% of all mappable clones identified and assembled into a minimum of 220 contigs.[69] However, the results obtained deviated slightly from theoretical predictions[68] in that a lower than expected fraction of the genome was covered by the assembled

contigs. This result might have been caused by a non-random genome representation in the BAC library used. An intriguing 200-kb periodicity of over- and under-represented regions has been observed in an independent study.[99] A total of more than 3000 hybridization experiments was performed on a 10 752 clone BAC library[41] representing ca. 7 genome equivalents. The results of 2723 hybridization experiments were included in the final map, which were complemented by 272 genetic marker data.[70]

In the second approach, a high-throughput BAC DNA fingerprint analysis was performed on a set of 21 403 *Arabidopsis thaliana* BAC clones, of which 20 206 successfully yielded fingerprint data.[97] Using the FPC software[100] for automated assembly of contigs based on the fingerprint data and by manual editing, a total of 169 contigs containing at least 3 BAC clones and another 124 contigs containing 2 BAC clones were assembled. These 293 contigs contained 19 909 BAC clones.

To assemble the final map, the results obtained by the hybridization experiments were merged with the BAC fingerprint data by querying the latter for the presence of BAC clones not identified in the hybridization experiments and for clones closing gaps between the previously established contigs. Ninety-nine connections shown in the map were inferred exclusively from this information. In addition, the fingerprint data were particularly useful to solve conflicting hybridization data (due to cross-hybridization) and to assemble and extend contigs of clones containing repetitive sequences. The map (displayed at http://www.mpimp-golm.mpg.de/101/mpi_mp_map/access.html) consists of 27 contigs that cover the entire *Arabidopsis thaliana* nuclear genome, except for the presumptive centromeric regions, nucleolar organization regions, and telomeric areas. The 27 contigs are distributed over the 10 chromosome arms leaving 14 gaps, 12 of which are bridged by YAC, P1 or transformation-competent artificial chromosome clones according to other maps already established for chromosomes II–V.[101–106]

This report demonstrates the strong advantage of having available two large sets of data generated by the use of different techniques and approaches (which proved to be complementary rather than redundant) to achieve the goal of rapidly and efficiently establishing a complete physical map of a complex genome.

ABBREVIATIONS AND ACRONYMS

BAC	Bacterial Artificial Chromosome
EST	Expressed Sequence Tag
PAC	P1-derived Artificial Chromosome
PCR	Polymerase Chain Reaction
PFGE	Pulsed-field Gel Electrophoresis
STS	Sequence-tagged Site
YAC	Yeast Artificial Chromosome

Nucleic acids are prone to fragmentation in the ionization process of mass spectrometry (MS). The cause can be found in the polar nature of this analyte class. Following the introduction of the so-called soft-ionization techniques of electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI) at the end of the 1980s, mass spectrometric analysis of nucleic acids has gained broader applicability. In combination with further developments of the associated instrumentation and optimized preparation and purification methods, a dramatic enhancement of the mass range, detection sensitivity, and resolution became possible – in routine analysis oligonucleotides up to a length of 50 nucleotides are accessible. At present the necessary quantity of sample is in the subfemtomole range.

This article describes the fundamentals of mass spectrometric analyses of nucleic acids and common applications, such as the analysis of noncovalent complexes, mixture analysis, different sequencing strategies and clinical diagnostics. The focus is on MALDI/MS (matrix-assisted laser desorption ionization/mass spectrometry).

1 INTRODUCTION

Characterization of nucleic acids by MS has always been both a challenging and promising endeavor. Since 1962, when the first mass spectra of nucleosides obtained with electron impact mass spectrometry (EI/MS) were reported[1] MS has gained importance in nucleic acid analysis.[2–4]

Although the classical ionization techniques (electron impact (EI) and chemical ionization (CI)) were limited in analyte size to dinucleotides, they were successfully employed for the structural analysis of nucleic acid constituents (i.e. nucleobases, nucleosides, nucleotides) and had their significance especially in the elucidation of posttranscriptional processings of RNA and DNA.[5] The limitation to dinucleotides is a result of the polar nature of the analyte and the elevated tendency to fragmentation (thermal decomposition predominates volatilization).

Chemical derivatization of the analyte was often necessary to enhance the volatility and to reduce fragmentation for MS examination.[6] Hunt et al.[7] intensively studied per(trimethylsilyl) derivatized dinucleoside monophosphates with EI/MS. In addition to the molecular ions they observed sequence-specific fragment ions. As dinucleotides are the smallest nucleic acid subunit that contains sequence information, these studies paved the way for direct MS sequencing. The investigation of all four underivatized di-2′-deoxyribonucleoside monophosphates showed no molecular ions, but fragment ions in terminus-related intensities.[8] However, diribonucleoside monophosphates were found to be much more stable, a feature attributed to the 2′-hydroxyl group.[9] Unprotected dinucleotide monophosphates could be analyzed with field desorption (FD) MS,[10] but it was found that this technique was experimentally difficult to handle with low run-to-run reproducibility.[11]

The analysis of oligonucleotides became feasible with the introduction of plasma desorption (PD), secondary ion (SI), and fast atom bombardment (FAB) MS.

Positive ion spectra of plasma-desorbed protected oligonucleotides showed mostly cationized quasimolecular ions[12,13] with a size limit of nine nucleotides.[14] In the negative ion mode distinctive fragment ions could be observed in addition to the deprotonated quasimolecular ions. The fragmentation pattern showed two complementary series retaining either of the two termini of the nucleotide strand. Beginning with the more intense series of fragment ions containing the 5′ terminus, these fragments bear the phosphate group at their 3′ end after cleavage of the respective 5′ C–O bond and, correspondingly, the 3′ terminus series carries the phosphate group at the 5′ end after cleavage of the 3′ C–O bond.[12,15] SIMS (secondary ion mass spectrometry) revealed the

attachment of Na^+ and Cs^+ to the molecule in the positive ion mode and intact quasimolecular ions in the negative ion mode.[16] Wu et al.[17] reported an enhanced ionization efficiency with SIMS if the analyte was mixed with a typical MALDI matrix (e.g. dihydroxybenzoic acid). This technique made it possible to detect a DNA 26-mer with only minor fragmentation. The pioneering work on MS oligonucleotide sequencing was performed by Grotjahn et al. who compared the mass spectra of more than 100 oligomers obtained by negative ion mode FAB/MS (fast atom bombardment/mass spectrometry). These workers deduced rules for deriving sequence information from fragment ion patterns.[18,19] Two major fragment ion series were detected: one more intense with the so-called 5′ sequence ions bearing a 5′ phosphate group, and a second one with the phosphate group at the 3′ end (3′ sequence ions). It is noteworthy that this description may be misleading: the 5′ sequence ions (3′ sequence ions) only carry the phosphate group of the cleaved phosphodiester bond at their 5′ end (3′ end), but contain the 3′ terminus (5′ terminus) of the oligonucleotide. Although additional fragmentation (−18 Da, explained as loss of water and +80 Da, described as $+HPO_3$ artifacts) was observed, bidirectional sequencing based on these two distinct fragment ion series was proposed. This concept for sequencing unknown oligonucleotides relied on the assignment of the more intense series to the so-called 5′ sequence ions. It was reported that this was indeed the more intense series for 8-mers but not for 2–4-mers. Other researchers also questioned the predominance of the 5′ series.[20,21] The complete bidirectional sequence information could be obtained for up to a 10-mer using about 10 nmol of sample.[19,22] Although efforts were made to increase the accessible mass range of oligonucleotides for FAB/MS the biggest detected intact oligonucleotide was an RNA 24-mer.[23] A detailed comparison of these ionization methods for short oligonucleotides with special consideration of the fragmentation is given by Crain.[2]

The introduction of ESI by Fenn et al.[24] and MALDI by Karas and Hillenkamp[25] in the late 1980s opened a new chapter in MS nucleic acid research. Further development of the associated instrumentation in combination with optimized preparation and purification methods led to dramatic increases in the accessible mass range, resolution, and sensitivity.[26–30]

1.1 Characteristics of Nucleic Acids Under Mass Spectrometric Conditions

ESI and MALDI exhibit similarities but also differences due to the respective ionization technique. In ESI, an analyte solution is sprayed through a needle into an electrical field and ionized via repetitive coulombic bursting of the generated droplets until the fully desolvated analyte ions finally enter the mass analyzer. For a MALDI analysis, the analyte solution is mixed with a matrix (organic substance in a high molar excess) and deposited on a metallic sample support. For solid matrices used predominantly in MALDI with ultraviolet (UV) laser wavelengths (UV/MALDI), the volatile solvent is evaporated leaving a polycrystalline sample behind. Vacuum-stable liquid matrices such as glycerol are used predominantly in MALDI with infrared (IR) wavelengths (IR/MALDI) and the matrix/analyte preparation is transferred directly into the spectrometer. Both analyte and matrix molecules are desorbed and ionized in an interaction of the sample with a high intensity laser light pulse of nanosecond duration.

In solution, the polyanionic backbone of nucleic acids is fully dissociated as a result of the pK_a value of the backbone phosphates being less than 1 (for a comparison, phosphoric acid has a pK_a of 2.1).[31] The pK_a values of all protonated nucleobases but the uracil (U) derivatives ($pK_a \approx 10$) vary from 3.5 to 5.[31] For ribonucleosides the pK_a values are 4.2 for cytidine, 3.5 for adenosine, and 2.4 for guanosine. These values are only slightly less than those for the deoxyribonucleosides. Due to the electrostatic interaction of the negatively charged phosphodiester groups with the protonated bases, the respective values are decreased in nucleotides by 0.2–0.5 pK units.[31] These variations may occur because of the more complex interactions possible within bigger molecules. It should be kept in mind that ionic strength[32] and temperature[33,34] both influence the ionization constants. Kochetov and Budovskij[35] evaluated the possible protonation sites of the nucleobases and stated that they are N1, N3 and N7 for adenine (A), N3 and N7 for guanine (G) and N3 for cytosine (C). The same authors reported that X-ray, spectroscopic, and NMR studies revealed N1 in A and N7 in G as favored protonation sites (Figure 1).[35]

As the molecules are transferred into the gas phase for mass spectrometric analysis, the gas-phase acidities and basicities must be considered for the interpretation of the mass spectra, especially to account for process-induced fragmentation. Greco et al. determined the following order of proton affinities for deoxyribonucleoside 5′ monophosphates (dNMPs): dGMP (234.4 kcal mol^{-1}) > dAMP (233.6 kcal mol^{-1}) ≈ dCMP (233.2 kcal mol^{-1}) ≫ dTMP (224.9 kcal mol^{-1}).[36] Similar values can be expected for the related ribocomponents. The proton affinity of the phosphodiester group has not been determined experimentally, but was deduced from the known value for triethylphosphate as 220–225 kcal mol^{-1}.[37] The following can be concluded for singly protonated or deprotonated ions (usually observed in MALDI/MS). In the positive ion mode (protonated quasimolecular ion), the most stable structure is the one in which all phosphodiester groups

Figure 1 (a) Nucleoside structures with the numbering of the ring atoms in the bases and of the carbon atoms in the sugar moieties: I adenosine; II guanosine; III C; IV with R′ = CH_3 thymidine, and with R′ = H uridine. The sugar moiety is deoxyribose with R = H and ribose with R = CH_3. R = F indicates a 2′ fluorine modification. An exchange of N in position 7 for C in structures I and II leads to the respective 7-deaza purines. (b) Structures of the 4-mer are (left) DNA ACGT and (right) RNA ACGU. The differences between DNA and RNA are printed in bold letters.

are neutral and the proton is located on either G, A, or C. Only for oligothymidylic acids are the proton affinities of the phosphodiester group and the base too similar in value to predict a localization of the proton. It is noteworthy that interactions between phosphate groups and nucleobases are probable, resulting in the transient formation of zwitterions in dependence of the respective proton affinities for both the positive and negative ion mode. Rodgers et al. have calculated the gas-phase acidities of nucleobases in dideoxyribonucleotides and for the phosphodiester group to obtain G (333.4 kcal mol^{-1}) > thymine(T) (344.1 kcal mol^{-1}) ≈ C (345.6 kcal mol^{-1}) > A (349.0 kcal mol^{-1}) and 329 kcal mol^{-1} for the phosphodiester group.[38] Hence, in the negative ion mode the charge is expected to be located on one of the phosphodiester groups of the oligonucleotide.

Another characteristic of nucleic acids is the strong affinity towards metal ions. Binding sites are the oxygen

and nitrogen atoms in the nucleobases and, to a lesser extent, the phosphate and sugar moieties.[39] The importance of metal binding of nucleic acids in vivo lies in the specific interaction with proteins and in the stabilization of the secondary structure. However, this property affects the quality of the mass spectra. Heterogeneous cation attachment, such as the ubiquitous Na^+ and K^+, decreases sensitivity, resolution, and mass accuracy. Instead of just the protonated/deprotonated quasimolecular ion, the total ion current (TIC) is distributed over a multitude of ion species. As the mass differences between these different ions are relatively small, the separation of neighboring signals becomes increasingly difficult with increasing analyte mass until only the envelope can be resolved. Owing to the higher resolution of quadrupole analyzers (in the case of the detection of multiply charged larger analytes) when coupled to ESI sources, this effect is less pronounced there than it is for the singly charged MALDI ions in the time-of-flight (TOF) analyzer of MALDI instruments. However, impurities are often displaced from the crystalline rim of the sample to the microcrystalline center in MALDI sample preparations (purification by crystallization). ESI lacks this inherent purification mechanism. Moreover, ESI generates predominantly multiply charged ions. Therefore, cations present in the preparation give rise to ion series with the same charge state but a diversity of attached cations. This further complicates the mass spectrum. Therefore, careful sample handling and/or desalting procedures are vital for successful MS analyses.

Improvement in resolution and sensitivity of negative ion ESI mass spectra was first reported by Stults and Marsters.[40] Cation exchange with ammonium acetate via precipitation of the oligonucleotide led to a clear decrease in sodium salt formation for the tested DNA 30-, 48-, and 77-mers (Figure 2).

Desalting is also very beneficial for MALDI/MS. Exchanging metal cations with organic ammonium salts

Figure 2 Electrospray mass spectra of the 30-mer of sequence $H_2N-(CH_2)_6-PO_2H-$ATC GTT CCT TTG GCA TTC CTG ACT CAT CTA (a) before and (b) after ammonium acetate precipitation. turned out to be an effective solution for both ionization techniques. In the gas phase, these ammonium salts release ammonia, and the oligonucleotides are detected as free acids. This principle has been applied to both ESI and MALDI and to various classes of nucleic acid analytes.[27–29,41,42]

The purification and preparation depends on the chemical environment and the heterogeneity of the sample. Salts present in only small amounts can be suppressed by additives to the analyte solution (ESI/MS) and also to the MALDI matrix. The addition of ammonium tartrate or citrate to matrices such as 6-aza-2-thiothymine[43] (ATT), and to a mixture of 2,3,4- and 2,4,6-trihydroxyacetophenone[44] (THAP) has been shown to increase the analyte ion intensity. It is possible that this effect is due to enhanced ionization of the analyte,[44] more efficient incorporation into the matrix crystals,[45] or a reduction of cation attachment.[46] An elegant way to remove monovalent metal cations is the addition of cation-exchange polymer beads (BioRad™, Hercules, CA, USA) loaded with ammonium.[47,48] Both analyte and matrix solutions can be desalted with these beads. An on-target addition of a small aliquot of cation-exchange beads to the MALDI preparation further eliminates cations introduced from the sample support or from pipette tips.[47]

It was reported that the addition of *trans*-1,2-diaminocyclohexane-*N*,*N*,*N*′,*N*′-tetraacetic acid leads to a successful elimination of divalent cations from tRNAs for ESI/MS[49] but has only a minor effect for MALDI/MS.[50,51] Reversed-phase high-performance liquid chromatography (RPHPLC) (section 2.2.) has been used to desalt analyte solutions prior to ESI/MS analysis.[52] This approach offers advantages for shorter oligonucleotides with their lower precipitation efficiencies. Kussmann et al.[53] introduced a miniaturized version for a fast sample clean-up. The analyte is concentrated in a column (GelLoader™ tip, Eppendorf), packed with only a few microliters of Poros™ material (PerSeptive Biosystems, Framingham, MA, USA), washed and then eluted directly onto the MALDI target. For DNA and RNA a triethylammonium acetate buffer, pH 7, with acetonitrile–water was employed.[54] Similar microcolumns in a pipette tip are now commercially available (Millipore, Bedford, MA, USA).

Whereas fragmentation is less pronounced in ESI/MS, it clearly limits the accessible mass range for UV/MALDI. Although fragmentation occurs at all times during the MALDI/TOF measurement (section 2.4.) it is the metastable decay in the field-free drift tube that impairs routine analyses by peak broadening, loss of signal intensity, and therefore reduced resolution (Figure 3). This is particularly marked in instruments with an ion

Figure 3 Comparison of MALDI negative-ion reflectron-TOF-mass spectra of oligodeoxynucleotides with increasing sequence length with 3-hydroxypicolinic acid (3-HPA) and a laser wavelength of 355 nm: (a) 12-mer 5′-dCGC GAT ATC GCG-3′; (b) 26-mer 5′-dCTA CTC TCA CTA CGC GCA AGC TAC CG-3′; (c) 40-mer 5′-dTAC AGA TTT TAT GTT TAT TTA TGT TTG CTT TTC AAA AGGC-3′. In spectrum (c) in addition to the secondary electron signal of the secondary electron multiplier, a second detector signal (SI signal) is observed and assigned, due to the detection process of higher masses. (Adapted from E. Nordhoff et al., *Nucleic Acids Res.*, **22**, 2460–2465 (1994) with permission from Oxford University Press, Copyright 1994.)

reflector which must be used for large oligonucleotides in IR/MALDI.

It was found that fragmentation increases with the mass of the analyte and is strongly dependent on base composition and applied matrix–laser wavelength combination.[48,55,56] Three groups determined the order of nucleobase stability T(U) ≫ C > A, G under MALDI conditions,[48,55,57] and one group found the order T(U) ≫ A > C, G with A and C reversed.[56] The following

Figure 4 (a) Suggested reaction schemes for the fragmentation of oligonucleotides with the fragment ions assigned using McLuckey nomenclature. (Adapted from E. Nordhoff et al., *J. Mass Spectrom.*, **30**, 99–112 (1995) with permission of John Wiley & Sons Limited, Copyright 1995.) (b) Putative backbone cleavages and (c) the loss of base. (Reprinted from S.A. McLuckey et al., *J. Am. Soc. Mass Spectrom.*, **3**, 60–70 (1992) with permission from Elsevier Science, Copyright 1992 by American Society for Mass Spectrometry.)

oligonucleotide stability order was observed: oligouridylic (oligothymidylic) acid > RNA > DNA.[48] The higher stability of RNA relative to DNA can be explained by the balancing effect of the 2′-hydroxyl group on polarization of the *N*-glycosidic bond, induced by protonation of N7 of the purine bases and N3 of C. It was speculated that the 2′-hydroxyl group may also sterically hinder the base loss. This explanation can be ruled out because nucleic acids containing C-arabinose (with the hydroxyl group in the *cis* position) were found to exhibit a similar stability.[58,59] Base protonation was soon found to be the initial step of ion fragmentation in the positive ion mode, leading to cleavage of the *N*-glycosidic bond, often followed by backbone cleavage (Figure 4).[48,55,60–62] This figure also gives the fragment assignment by McLuckey et al.[63]

For the negative ions the details of the fragmentation mechanisms are still under discussion. A positional dependence of the protonation of base (charge remote fragmentation) has been suggested.[64]

The suppression of fragmentation can be accomplished by modifying either the nucleobase, the sugar, or the phosphodiester moieties. 7-Deaza-purine nucleotides, long employed in gel-electrophoresis, afforded a substantial improvement in ion stability.[61,65] However, due to the participation of N3 of C in base pairing, the corresponding deaza-C-analog is incompatible with enzymatic reactions. It was shown that, at least for mixed-sequence 4-mers, the loss of C is comparable in magnitude to the loss of A and G. Therefore, the stabilization of this base is required as well.[62] Exchange of the sugar moiety for arabinose and 2′-fluorine modification of ribose have also been reported.[58,59] Unfortunately, the combination of these modifications with enzymatic reactions turned out to be problematic.[66] Alkylation of the phosphate backbone

to reduce an interaction of the acidic protons with the bases was demonstrated to be effective for shorter oligonucleotides.[67] The efficiency of this approach to longer oligomers remains to be demonstrated. The choice of the matrix also has a strong influence on the fragmentation of nucleic acids under MALDI conditions. Since its introduction by Wu et al.,[68] 3-HPA is the matrix of choice for MALDI mass spectrometric measurements of DNA and RNA because of the limited prompt and metastable fragmentation observed with this matrix. Some prompt fragmentation was shown to take place for this matrix, but fragment ions are not detected because further serial cleavages occur leading finally to low-mass fragments.[59] A few other matrices, such as ATT and several di- and THAPs, have found to be useful for special cases of nucleic acid analysis. It is fair to state, however, that metastable decay remains the main problem for UV/MALDI/MS of nucleic acids.

1.2 General Characteristics of Mass Spectra

DNA and RNA are detected as protonated or deprotonated quasimolecular ions in MALDI/MS. Generally, singly charged ions $[M \pm H]^{+/-}$ constitute the base peak in MALDI mass spectra, although multiply charged ions $[M \pm nH]^{n+/-}$ and unspecific oligomers (singly and multiply charged, $[mM \pm nH]^{n+/-}$) are observed. The occurrence of multiply charged ions is more pronounced in the negative ion mode.[57] For most matrices the negative ion mode yields higher signal intensities, with the exception of 3-HPA where the signal intensities are comparable for both ion modes.[57,69] Matrix signals often dominate the low-mass range of the spectrum, increasing in mass and intensity with the applied laser fluence. A characteristic of ESI is the generation of multiply charged ions. As a rule of thumb, about one charge is present per 1000 Da of ion mass and, therefore, the mass spectrum of every single compound consists of several signals reflecting different charge states of the analyte. However, the charge distribution is strongly dependent on the molecular mass of the analyte, the solvents used, and the instrumental parameters. ESI mass spectra are commonly deconvoluted to determine the peak shape of the equivalent singly charged ion and the molecular weight. In combination with high-performance liquid chromatography (HPLC) the display of the TIC versus the retention time yields a chromatogram of the sample. Each signal of this total ion chromatogram usually consists of several mass spectra depending on the scanning time of the instrument (see Figure 7). In ESI/MS the negative ion mode generally provides higher signal intensities than the positive mode.

2 APPLICATIONS

The accessible mass range, sensitivity, and resolution determine the usefulness of MS in competition with other analytical techniques. The continuing improvements of these parameters have made MS of nucleic acids a widely used tool for a broad range of applications. In addition to accurate mass determination sequencing of polynucleotides, clinical and forensic diagnostics and the analysis of biologically relevant noncovalent complexes have become feasible. Sensitivity has been increased to the subfemtomole level using miniaturized sample preparation techniques.[70,71] Resolution has made a great leap forward with the implementation of delayed ion extraction[72] (DE) in MALDI/TOF/MS. For DNA up to about 50 nucleotides in length, enhanced resolution has been demonstrated.[73–76] In addition to better instrumental resolving power, DE leads to a reduced fragmentation in the initial field-free expansion of the generated plume. This further contributes to an increased mass accuracy[75] and sensitivity.[76]

2.1 Mass Range

In MALDI/MS, fragmentation of the analyte and cation attachment are the main factors limiting both mass range and resolution. Reduced efficiency of ionization[69] and detection may also hamper the analysis of large molecules. Nevertheless, the analysis of DNA up to 50 nucleotides in length by UV/MALDI/MS with a resolution of approximately 1000 FWHM (full-width at half-maximum) for this mass range has become routine. For DNA exceeding 80 nucleotides the resolution quickly decreases to 60–20 FWHM. The detection of a 461-mer in vitro transcript was reported by Kirpekar et al. after removal of the 5′ phosphate groups with calf intestine phosphatase to increase homogeneity and sensitivity.[77] The investigation of double-stranded DNA (dsDNA) exceeding 200 base pairs (bps), generated by restriction enzymes from plasmid DNA, was reported by Bai et al. The sample was prepared on a Nafion™ membrane with 3-HPA as the matrix.[78,79] Liu and colleagues coated the sample support with nitrocellulose (NC) and observed an improvement in the analysis of complex dsDNA mixtures with up to 622 bp using a 4 : 1 molar ratio of 3-HPA and PA (picolinic acid).[80,81] Furthermore, the detection of up to 500-mer ssDNA (single-stranded DNA) PCR (polymerase chain reaction) products was reported by Tang et al. with mixtures of 3-HPA and PA on a standard sample support.[82] Ross and Belgrader were able to detect a ssDNA 268-mer PCR product with a mixture of 3-HPA and PA in a solution of ammonium citrate and acetonitrile. The key to this successful analysis was the purification and isolation of a

single-stranded PCR product by affinity capture using streptavidin-coated magnetic beads.[83] In most cases only the dehybridized single strands are detected under the given MALDI conditions. Most of the individual strands of dsDNA exhibit only a small mass difference. For higher-mass analytes, this mass difference cannot be resolved further, leading to additional peak broadening. To avoid the severe fragmentation observed for larger oligonucleotides in UV/MALDI, Berkenkamp et al. used IR/MALDI with glycerol as the matrix and an Er/YAG laser with a wavelength of 2.94 μm for the analysis of restriction enzyme digests of plasmid DNA of more than 2000 nucleotides.[71] They observed a dramatically lower fragmentation under these conditions. However, so far mass resolution is limited to only 50–100 throughout the mass range representing about 100 to 1500 nucleotides (Figure 5).

Using ESI, the detection of intact highly charged DNA ions in the megadalton range has been demonstrated. Ions exceeding 1 MDa were detected by Fourier transform ion cyclotron resonance mass spectrometry (FTICR/MS)[84] and a TOF analyzer with a charge detector.[85] Extremely high values for the mass resolution have been obtained by FTICR/MS, but the heterogeneity of the charge states of the trapped ion population complicates the interpretation of the spectra.[86] Chen et al. succeeded in the detection of coliphage T4 DNA ions by FTICR/MS.[87] In this case the charge state of an individual highly charged anion could be determined by analyzing the decrease of the charge state over a given time interval. For the T4 DNA a charge state of 31 530 and a mass of 90.9×10^6 Da could be determined in this manner with a precision of 10%. In a subsequent work Cheng et al. reported the detection of pGEM-5S plasmid DNA. Determining a mass of 1.5 MDa (calculated 1.946 MDa) these workers reduced the uncertainty to ca. 3%.[88] Nonetheless, the uncertainty in determining the charge state and hence the molecular weight remains a problem in the analysis of large nucleic acids by ESI/FTICR/MS. Fuerstenau and Benner generated ions from plasmid and phage DNA ranging from 2.8 to 31 MDa by ESI.[85] The analyzer was a TOF mass spectrometer equipped with a novel charge-sensitive detector that allows for an independent determination of the m/z ratio and the charge of the ion. With this detector (a Faraday cage-like metal tube) the image charge signal of an individual ion is amplified by a low-noise charge-sensitive amplifier and the m/z corresponds to the time that the ion needs to pass the detector tube. Again, the uncertainty in determining the charge states decreases the mass accuracy. Refining this technique has led to the development of a gated electrostatic ion trap,[89] in which an individual ion is trapped between two plates and, therefore, traverses the detector tube

Figure 6 Histogram of the average mass obtained from each of 549 pBR322 trapped ions. (Reprinted from W.H. Benner, *Anal. Chem.*, **69**, 4162–4168 (1997) with permission from American Chemical Society, Copyright 1997.)

several times. The single measurements of charge state and m/z can be averaged and hence reduce the signal-to-noise ratio compared with a single measurement. Figure 6 shows the histogram of the average mass acquired from 549 trapped pBR322 plasmid ions. The signal at mass 2.88 Da corresponds to the sodiated (protonated) pBR322 ion and the signal at 5.85 Da to the dimer.

2.2 Mixture Analysis and Combination of Mass Spectrometry with Separation Techniques

The ability to analyze mixtures is an important feature because many samples, such as those from a Sanger reaction, contain a number of individual species of different mass. Furthermore, the impurities of real-life samples and the heterogeneity (e.g. different modifications) of the sample can be determined. One important point for the analysis of mixtures in which the analytes are present in different concentrations is the dynamic range. This parameter is dependent on the analyzer used and describes the concentration difference between two components when both are still detectable – one signal distinguishable from the background noise (e.g. a signal-to-noise ratio greater than 2) and the other signal near saturation. Another critical point in mixture analyses with MALDI is that higher-mass analytes often require higher desorption laser fluxes. At these fluxes, the resolution of lower-mass analyte signals may already be lower than that attainable for the pure low-mass compounds. As mentioned before, the difficulty in analyzing larger molecules may have its cause in a higher degree of fragmentation and a decreased detection efficiency.[69] Larger molecules may also be in competition with smaller molecules for the charges. For an easy interpretation of the spectra it is beneficial if every component has only one major charge state, i.e. one peak in the MALDI mass spectrum. Therefore, the positive ion mode should be preferred for MALDI/MS, particularly with 3-HPA as the matrix, as in the negative ion mode multiply charged ions are observed to a larger extent.[57] This is also the reason why ESI/MS with its multiply charged ion distributions is inferior to MALDI/MS for mixture analyses if the masses of the mixture components extend over a wide mass range. However, ESI is superior for the analysis of mixtures which vary only slightly in mass, because of its inherently higher-resolution mass analyzers. Therefore, the demand on resolution depends on the expected mass differences between adjacent peaks. An elegant way of performing mixture analysis is on-line coupling with different separation techniques such as chromatography and electrophoresis.[90] In addition to the separation of molecules which may differ only slightly from each other, the elimination of sample impurities is a great advantage of such combinations. Electrospray is especially suited to the combination with liquid chromatography because the analyte is ionized from solution.

Figure 7 Analysis of synthetic pBR322 oligonucleotides by HPLC/ESI/MS. (a) Total ion chromatogram, (b) raw mass spectrum, (c) deconvoluted mass spectrum. (Reprinted from A. Apffel et al., *Anal. Chem.*, **69**, 1320–1325 (1997) with permission from American Chemical Society, Copyright 1997.)

However, the buffers have to be optimized with respect to both the chromatographic separation and the MS ionization steps. An ammonium acetate or triethylammonium acetate–acetonitrile gradient was used in a concentration of 5–10 mM by Bleicher and Bayer.[91] The good compatibility with the ionization was compromised by the low separation efficiency. Apffel et al.[92] introduced a gradient system with 1,1,1,3,3,3-hexafluoro-2-propanol adjusted to pH 7 with triethylamine, which yielded a superior separation resolution and also higher ionization efficiency (Figure 7).

This buffer system was also used by Griffey et al.[93] for the characterization of phosphorothioate (replacement of the nonbridging oxygen of the phosphate backbone by sulfur) oligodeoxynucleotides from in vivo metabolism in pig kidney. The coupling of HPLC to an ESI ion trap made it possible to determine the base compositions of the respective metabolites of the injected phosphorothioate DNA. Sequence information could also be obtained via fragmentation. Thus 3′ and 5′ exonuclease activity and, presumably, also endonuclease activity as well as the addition of single deoxyribo- and ribonucleotides were observed. For MALDI/MS both off-line and on-line coupling with chromatographic and electrophoretic techniques have been reported. On-line coupling is less common and requires modification of the preparation technique.[94,95] A detailed discussion on combining MALDI with liquid separation techniques is available.[96]

2.3 Noncovalent Complexes

An understanding of biomolecular interactions helps in comprehending life on the molecular level. Noncovalent interactions between biomolecules govern all cellular processes. Knowledge of the recognition between proteins and nucleic acids, such as between polymerase and DNA, is of great importance to the understanding of cell division and cell proliferation. The detection of noncovalent complexes using MALDI/MS is not possible with the preparation protocols mentioned so far. This indicates that the choice of matrix and preparation are of vital importance. A general characteristic of MALDI mass spectra is the frequent observation of the most probable gas-phase-generated unspecific analyte oligomers. These oligomer signals are generally much weaker than the quasimolecular ion peaks. Furthermore, their intensities decrease with increasing degree of oligomerization. Although these characteristics can aid in distinguishing specific complexes from unspecific adducts, great care has to be taken to verify the nature of noncovalent complexes, e.g. by competition experiments and careful attention to the relative signal intensities.

The first noncovalent nucleic acid complex observed by MALDI was reported by Lecchi and Pannell. They

Figure 8 MALDI spectrum of EcoR1 12/16 adapter with ATT as the matrix. The DNA dimer region with 2,4,6-THAP as the matrix is shown for comparison at a 20-fold expansion in the inset. Only peaks from the single-stranded oligonucleotides were observed with 2,4,6-THAP. The ion at 8609.3 (calculated value 8606.6) in the ATT spectrum represents the detection of dsDNA. (Adapted from P. Lecchi and L.K. Pannell, *J. Am. Soc. Mass Spectrom.*, **6**, 972–975 (1995) with permission from Elsevier Science, Copyright 1995 by American Society for Mass Spectrometry.)

succeeded in detection of the EcoR1 adaptor double-stranded 16/12-mer in addition to the single strands in 1995 using ATT as the matrix.[43] No unspecific oligomerization was observed. Control experiments with 3-HPA and THAP showed no signal for the double strand (Figure 8).

Digestion with nuclease S1, which is much more active in cleaving ssDNA than dsDNA, was used to show that the single strands, as well as the duplex, originated from the original sample rather than being generated by the MALDI process. The same authors reported later that those chemicals having a stabilizing effect on oligonucleotide structure in solution also improve the detection of specific complexes. Thus, calcium as well as spermidine substantially enhanced the detection of a dsDNA 12/16-mer, whereas the denaturing agent formamide completely prevented detection of the complex.[97] It was also stated that the stabilizing effect of calcium on the duplex is somewhat counteracted by a loss of mass resolution due to cation attachment. Kirpekar et al. investigated the applicability of both UV/MALDI and IR/MALDI for the detection of dsDNA.[98] For double strands up to 70 bp, UV/MALDI and the matrix ATT were found to be superior. However, double strands exceeding 70 bp could be better analyzed by IR/MALDI because of the strongly decreased fragmentation and higher sensitivity. As pointed out by Lecchi and Pannell.[97] agents stabilizing the structure in solution (40 mM ammonium acetate or 40 mM tris(hydroxymethyl)aminomethane (Tris)–HCl) were found to have a positive effect on the detection of the

Figure 9 IR/MALDI reflectron TOF mass spectrum of a mixture of dsDNA fragments recorded from a glycerol/ammonium acetate matrix. The sample was generated by digestion of the plasmid pBluescript-KS$^+$ with the restriction enzymes *Bgl*I and *Rsa*I. (Reprinted from F. Kirpekar et al., *Anal. Chem.*, **71**(13), 2334–2339 (1999) with permission from American Chemical Society, Copyright 1999.)

complex. Further addition of a destabilizing agent such as succinic acid (acidic denaturation) hindered detection of the complex. The largest dsDNA detected was a 1.05 kbp fragment of about 645 kDa in mass. The authors stated that the quality of spectra with fragments exceeding 1 kbp of length is significantly reduced. Figure 9 shows the IR/MALDI reflection TOF mass spectrum of a mixture of dsDNA generated by the digestion of the plasmid pBluescript-KS+ with the enzymes *Bgl*I and *Rsa*I using glycerol/ammonium acetate matrix.

As an example of a biologically relevant protein–nucleic acid complex, Gruic-Sovulj et al. reported the specific complex between aminoacyl tRNA synthetases (serine (SerRS) and tyrosine (TyrRS)) and their cognate tRNAs ($tRNA^{Ser}$ and $tRNA^{Tyr}$).[99] In that case, the specificity of the complexes was verified by competition experiments testing both tRNAs against a given synthetase.

Because of the gentleness of the desorption ESI lends itself even more than MALDI to the detection of noncovalent associations. Instrumental parameters such as temperature and declustering voltage of the ion source as well as the chemical environment of the sample have a great influence on the success of the analysis. As nonspecific complexes have also been reported for this ionization technique,[100–102] care should be taken in spectra interpretation. Analysis of noncovalent interactions of oligonucleotides by ESI have been reported since 1993.[103–105] Schnier et al.[106] supplied evidence for the occurrence of Watson–Crick bps of the dsDNA in the gas phase by measuring the dissociation kinetics using blackbody IR radiative dissociation in a Fourier transform instrument. The activation energies for dissociation of specific noncovalent complexes were significantly higher than those obtained for nonspecific associations. Moreover, a correlation between the gas-phase dissociation activation energies and the dimerization enthalpies in solution was observed. Interaction between dsDNA and metal ions[107] as well as drugs[108–110] have also been investigated and collision-induced dissociation (CID) of the complexes was found to be a facile approach with which to verify the correctness of the noncovalent binding.[110–112] Cheng et al. determined the binding stoichiometry of gene V protein from bacteriophage f1 with oligonucleotides through competition experiments.[113] Oligonucleotides with 16 nucleotides showed a stoichiometry of 4 : 1 (protein monomer/oligonucleotide), whereas oligonucleotides with 15 nucleotides and lower had a stoichiometry of 2 : 1. Control experiments at low pH values (acid-induced denaturation) displayed no complex formation, whereas the complexes were unaffected by an increase of the interface capillary temperature of the instrument. These results agreed with those obtained by size-exclusion chromatography. Furthermore, competition experiments involving the transcription factor PU.1 DNA binding domain (PU.1-DBD) and dsDNA

Figure 10 ESI/MS spectra of PU.1-DBD and mixtures of DNA in 10 μM ammonium acetate (pH 7.0) acquired on a fourier transform ion cyclotron resonance (FTICR) instrument. Mixtures contain (a) PU.1-DBD (5 μM), 17 bp DNA (15 μM), and 19 bp DNA (20 μM); (b) PU.1-DBD (3 μM), 17 bp DNA (10 μM); and 19 bp DNA (200 μM). Abbreviations in the spectra: D = dsDNA, B = heavy strand of dsDNA, and w = wild-type and m = mutant-type DNA sequences. (Reprinted from X. Cheng et al., *Anal. Biochem.*, **239**, 35–40 (1996) with permission from Academic Press, Copyright 1996.)

containing (17 bp, wild type) or missing (19 bp, mutant) the recognition motif revealed the specificity of the complex.[114] Even for a 20-fold excess of the dsDNA lacking the binding motif only the specific complex was detected (Figure 10).

The stability of a specific noncovalent tryptophan repressor-DNA-complex was shown by Potier et al.[115] with CID. Dissociation of this protein-dimer/operator DNA complex could be achieved only under conditions which also cleaved covalent bonds, probably depurinating the DNA.

These examples for the detection of noncovalent complexes illustrate that MS is a valuable method as long as the specificity of the complex can be verified and the complex reflects the true solution structure. Information on binding stoichiometry, dissociation constants,[116] base composition, and even structural information can be obtained in addition to proof of the existence of the complex itself.[117–119]

2.4 Sequencing Approaches

Because of the accessible mass range and the decrease in resolution with increasing length of nucleic acids, the available mass spectrometric sequencing techniques present no challenge to the conventional techniques used, e.g. in the human genome project. Nevertheless, MS is an accurate, rapid, and sensitive tool ideally suited for sequencing shorter nucleic acids. Consequently, MS sequencing holds great promise in the fields of clinical diagnostics, forensics, paternity analysis, livestock breeding, plant cultivation, and cell line typing. One of the advantages of MS over gel-based Sanger sequencing lies in the fact that the mass is an intrinsic property of the molecule rather than an extrinsic one such as electrophoretic mobility. Furthermore, the mass can provide evidence for the occurrence of modifications in the analyte and an accurate mass measurement allows for the determination of base composition, as was shown by Pomerantz et al.[120] Aaserud et al.[121] demonstrated that analyzing dsDNA with ESI/FTICR defines or restricts the bp composition up to 600 bp. Sequencing strategies can be divided in three categories: sequencing by process-induced fragmentation, sequencing via chemically generated fragments, and sequencing using enzymatic reactions.

2.4.1 Sequencing with Process-induced Fragmentation

Although fragmentation hampers MALDI analysis of nucleic acids to a great extent it can also be capitalized on to gain sequence information when the fragmentation is controlled. The emphasis lies on the term controlled. The desired cleavage pattern should be a consecutive disjunction of the nucleotide constituents at specific bonds. An additional, but less intense, loss of bases and phosphate groups can help to characterize and locate possible modification sites. However, multiple base losses and predominance of certain nucleotide cleavages over others will only disturb or even prevent sequence determination. It has to be kept in mind that the impact of fragmentation on the mass spectrum depends on the decay time in relation to the instrumentally determined time frame for the analysis. Depending on the mass, the flight time of an ion in a TOF mass spectrometer is in the microsecond to low millisecond range. This dependence of the decay time constant is particularly pronounced for TOF analyzers. Therefore, a short description of their relevant properties is given here. More detailed information about mass analyzers is given in the instrumentation section of this encyclopedia.

2.4.1.1 Decay Time in Regions where the Electric Field is Nonzero These are primarily the region of acceleration right in the source and in the ion reflector. As a rule of thumb, fragments generated in these regions are distributed and are therefore unpredictable in mass. For TOF instruments with static ion extraction a fragment is termed prompt if its decay time constant is comparable to the generation time of its parent ion. Such fragment ions will encounter the full acceleration voltage and are detected at their correct m/z value in the mass spectrum. Ions that fragment shortly after the generation of the parent ions (fast fragments) up to the time until the parent ion leaves the accelerating region have an energy deficit and are, therefore, not detected at their correct mass in the spectrum. Ions resulting from this type of fragmentation are not suited for sequencing, because the true fragment masses cannot be determined.

2.4.1.2 Decay in Regions where the Electrical Field is Zero With the implementation of DE, ions with longer decay time constants can, however, provide valuable sequence information.[122] Fragments, generated during the delay time of typically a few hundred nanoseconds are detected at their true masses in the spectrum. These ions are called in-source decay (ISD) fragments. Metastable fragmentation occurs in the field-free drift tube of the TOF analyzer, i.e. after the parent ion has left the acceleration region (post-source decay (PSD)). These fragments continue to fly with very nearly the same velocity as the parent ion and are detected together with the parent ions in instruments with a linear geometry. This is also true if the mass difference compared to the parent ion is small enough for the associated energy deficit to be compensated by a reflectron. (A reflectron functions as an ion mirror and is used for compensating kinetic energy distributions of the generated ions.) With increasing mass loss, metastable decay

fragments manifest themselves in the spectra recorded with a reflectron TOF as a shoulder on the low-mass side of the peak. This type of fragmentation can be used for sequencing, if the deceleration potential of the reflectron is lowered in steps to display a small mass window of fragments whose mass can be determined with sufficient accuracy (PSD spectrum[123]).

Process-induced fragmentation has the advantage that no additional steps of preparation and sample handling are required. Nordhoff et al. have reported direct mass spectrometric sequencing of DNA up to 21 bases by IR/MALDI (Er/YAG laser, 2.94 μm) in the negative ion mode.[60] With low-picomole sample amounts and the matrix succinic acid three series of sequence-specific prompt fragmentations were observed (Figure 11).

In contrast to the explanation given by Grotjahn et al.,[19] Nordhoff et al. found that the 80 Da mass shift is not an HPO_3^+ artifact, but originates from an additional sugar moiety of the 3′ terminal phosphate group of d. Loss of a base is followed by cleavage of the 3′ C–O bond and results in fragments w and (a-B). Further loss of the furan moiety from (a-B) leads to d (see Figure 4). This sort of analysis is impeded by a relatively low shot-to-shot reproducibility, the competing high rate of metastable decay of the DNA, and the lack of fragmentation at T sites. Prompt fragmentation providing sequence information for DNA was also investigated in the negative ion mode

Figure 11 (a) Negative ion IR/MALDI reflectron TOF mass spectrum of a modified antisense-DNA 21-mer obtained with succinic acid as matrix. The defected d-, (a-B)-, and w-ions are assigned. The modified nucleoside d4T (2′,3′-dideoxy-2′, 3′-didehydrothymidine) has been added to the 5′ end of the antisense-DNA 20-mer by a 5′,5′ phosphate diester linkage. (b) Simplified fragmentation pattern derived from (a). (Adapted from E. Nordhoff et al., *J. Mass Spectrom.*, **30**, 99–112 (1995) with permission from John Wiley & Sons Limited, Copyright 1995.)

Figure 12 The MALDI spectrum of negative ions for a 28-mer 5′-CTT GGT AAA CAA ATT CTT GCT CGT TGA T-3′ oligonucleotide and its simulated spectrum of y-fragment ions. (Reprinted from Y.E. Zhu et al., *Rapid Commun. Mass Spectrom.*, **11**, 897–903 (1997) with permission from John Wiley & Sons Limited, Copyright 1997.)

with a UV laser (N_2) emitting at 337 nm.[124] Sequencing of DNA up to 35 nucleotides was demonstrated with the matrix systems 2-aminobenzoic acid and 2,4,6-THAP, both with dibasic ammonium citrate. Figure 12 shows the mass spectrum for a DNA 28-mer.

The full sequence can be read from the 5′ terminus, except for the last three nucleotides which are buried in the matrix background. Interestingly only the 5′ terminal w and y fragments appear in the spectrum. An additional loss of single bases was at least seen for a DNA 10-mer. Juhasz et al.[75] applied DE for sequencing DNA in the low-picomole range based on ISD in the negative ion mode. Whereas the combination of 3-HPA with an N_2 laser emitting at 337 nm showed no fragment ions of a DNA 11-mer, an ion series consisting of w, d, and also y ions was observed with PA at a laser wavelength of 266 nm (frequency quadruplet neodymium/yttrium–aluminum–garnet (Nd/YAG) laser). No a ions or base losses were detected. The w ions provided complete sequence information. Wang et al.[125] also applied ISD to sequence modified oligonucleotides with a combination matrix of 3-HPA and *N*-(3-indolylacetyl)-l-leucine at higher laser irradiances, significantly above the ion detection threshold. Sample amounts prepared were in the 30–160 pmol range. The fragmentation pattern of several modified DNAs composed of among others phosphorothioate and methylphosphonate (replacement of the hydroxyl group in the phosphate backbone by a methyl group) linkages, 2′-methoxygroups and DNA/RNA chimeras contain several different ion types for both ion polarities. The complete w series was observed accompanied by a, (a-B), and d ions and, at lower abundance, b, c, d, and z ions (Figure 13).

Figure 13 MALDI/TOF/MS of a 25-mer all-phosphorothioate oligonucleotide with the sequence 5′-CsTsCsTsCsGsCsAsCsCsCsAs TsCsTsCsTsCsTsCsCsTsTsCsT-3′ (with s indicating the phosphorothioate backbone). (Reprinted from B.H. Wang et al., *Int. J. Mass Spectrom. Ion Processes*, **169/170**, 331–350 (1997) with permission from Elsevier Science, Copyright 1997.)

For these samples no fragments were detected without DE, even at higher laser irradiances. An explanation given by the authors for the occurrence of a ions is the high density of matrix ions, radicals, neutrals, and analyte in the generated plume. The absence of this ion type in the measurements of Juhasz et al.[75] may be attributed to the fact that, in addition to the different matrix–wavelength combination, much lower sample amounts were prepared.

Sequencing by PSD can be achieved routinely for peptides and small proteins,[126] but this method is more difficult to apply to oligonucleotides. The first PSD spectra were reported by Kirsch et al.,[127] representing a DNA 5-mer analyzed in the positive ion mode. The spectrum is complicated by multiple base losses from the parent ion as well as from the fragments. As was observed for prompt fragmentation,[60,56] T sites in the molecule are only cleaved with very low intensities. Wang

Figure 14 Comparison of MALDI/PSD spectra for the structural isomers: (a) dTAGT and (b) dTGAT. (Reprinted from Z. Wang et al., *J. Am. Soc. Mass Spectrom.*, **9**, 683–691 (1998) with permission from Elsevier Science, Copyright 1998 by American Society for Mass Spectrometry.)

et al.[64] demonstrated the feasibility of PSD/MALDI to differentiate between structural isomers in the negative ion mode. Figure 14 illustrates the distinction between dTAGT and dTGAT by different w_2 and (a_3-B_3) ions.

PSD analyses of modified oligonucleotides have also been reported.[128,129] The coupling of MALDI to FTICR to investigate process-induced fragmentation of oligodeoxynucleotides with and without modifications have been reported by Buchanan and colleagues.[130–133] Unfortunately the lower fragment masses dominate these mass spectra.[133]

Under standard ionization conditions fragmentation is less prominent for ESI. However, fragmentation can be induced in the atmospheric pressure region between the ESI spray needle and the skimmer orifice (nozzle skimmer (NS) dissociation),[134] by collisional activation with inert gas molecules (i.e. by CID)[135] or by irradiation of the ions with an IR blackbody (or laser), usually from a CO_2 laser source, in the FTICR cell (infrared multiphoton dissociation (IRMPD)).[136] Quadrupole ion traps,[63,137–139] FTICR cells[136,140–142] and triple quadrupole instruments[143–145] have been used for these investigations. Fragmentation depends on the amount of energy transferred to the analyte. Owing to the higher collision energy in quadrupoles as compared with ion traps, fragmentation is more pronounced in the former, leading to a more complete sequence information. In FTICR instruments, the combined application of NS dissociation, CID, and IRMPD can provide complete sequence information up to 50 nucleotides and extensive fragmentation up to 108 nucleotides.[142] Figure 15 shows the spectra obtained with (a) NS dissociation and (b) CID of a DNA 8-mer.

For process-induced fragmentation the sample amount needed is often elevated, which is of concern for biological samples, but usually not for synthetic nucleic acids. The complexity of the mass spectrum and possible isobaric fragments of partially modified oligonucleotides somewhat limits these applications for routine complete sequencing of unknown samples. However, sequence verification of oligonucleotides can easily be performed with these approaches.

2.4.2 Sequencing with Chemically and Enzymatically Generated Fragments

Bond cleavage can also be achieved with enzymes or chemical agents added to the sample solution prior to MS analysis. One advantage of chemical over enzymatic cleavage is the less pronounced dependence on the secondary structure of the analyte. Furthermore, modifications of the backbone which lead to resistance against enzymatic degradation can be capitalized on to gain sequence information. Thus methylphosphonate DNA (used in antisense oligonucleotides) is resistant to nuclease digestions but can be sequenced by chemical means. Keough et al.[146] demonstrated the use of synthesis failure sequences for MALDI/MS to verify the identity of the synthetic product. Owing to the nature of the synthesis and the yield of 96–99% per synthesis cycle, a ladder consisting of the specific failure sequences is generated. In a subsequent paper Keough et al. combined failure synthesis analysis with exonuclease digestion and limited alkaline hydrolysis of the methylphosphonate linkages, allowing the complete sequence of a modified 18-mer to be read.[147]

Failure sequences allow one to read the sequence from the 5′ terminus of the oligonucleotide, whereas snake venom exonuclease successively cleaves nucleotides from the 3′ end. Sequence information can be completed by alkaline hydrolysis because the methylphosphonate linkages are exclusively susceptible to base-catalyzed hydrolysis. Polo et al.[148] demonstrated that the approach to sequence phosphorothioate-containing oligonucleotides with alkylating agents, first presented by Nakamaye et al.,[149] can be adapted for mass spectrometric analysis – 2-iodoethanol specifically alkylates

Figure 15 ESI mass spectra of 5′-CGA GCT CG-3′ with a calculated mass of 2409.45 Da. D and P refer to the deoxy and phosphate moieties, respectively. (a) NS and (b) CID spectra. (Adapted from D.P. Little et al., *J. Am. Chem. Soc.*, **116**, 4893–4897 (1994) with permission from American Chemical Society, Copyright 1994.)

phosphorothioate linkages, and cleavage occurs generating 3′ and 5′ fragment ladders. Although the complete sequence could be obtained for an all-phosphorothioate DNA 10-mer without being disturbed by the presence of internal fragments, the spectrum quality was poor, particularly the signal-to-noise ratio of the fragments. Limited alkaline hydrolysis was used by Hahner et al.[150] in combination with endonuclease cleavage of RNA to deduce sequence information. Alkaline hydrolysis alone provided nearly the complete sequence information for

Figure 16 Comparison of partial 3′ → 5′ and 5′ → 3′ exonuclease digestions analyzed by DE/MALDI. The time of each digestion is indicated. Both peak 1G in (a) and 33A in (b) correspond to the undigested 33-mer of sequence 5′-GCC AGG GTT TCC CCA GTC ACG ATG CAG AAT TCA. (a) 5′ → 3′ digestion with calf spleen phosphodiesterase. (b) 3′ → 5′ digestion with snake venom phosphodiesterase. (Adapted from I.P. Smirnov et al., *Anal. Biochem.*, **238**, 19–25 (1996) with permission from Academic Press, Copyright 1996.)

a synthetic RNA 25-mer. Because of the mass difference of only 1 Da between U and C, differentiating between them is difficult and a high resolution is vital, especially for large specimens. The use of base-specific endonucleases helped to solve this problem, but enzymatic specificity and efficiency may be compromised under the conditions used for MALDI analysis.[52] Tolson and Nicholson[151] applied hydrazine and aniline

as chemical agents for the specific cleavage of uridine sites in RNA to verify the sequence information obtained by exonuclease digestion. McCloskey and colleagues developed an ESI/MS-based approach[52,152] that involves cleavage with base-specific endonucleases to locate and determine modifications in RNA. Major contributions to the localization and characterization of RNA modifications were given by the McCloskey and Crain group.[153–155] Nonspecific endonucleases were used by Linscheid and colleagues in combination with capillary zone electrophoresis ESI[156,157] to determine the sites of styrene adducts. The use of exonucleases to generate sequence ladders[158] with subsequent mass spectrometric analysis was first reported by Pieles et al.[46] involving the phosphodiesterase from snake venom and calf spleen (the latter cleaves specifically from the 5′ terminus) and was soon adapted by others. Smirnov et al.[159] optimized the cleavage conditions specifically for the MALDI preparation and presented excellent quality spectra containing the complete sequence information of a DNA 33-mer (Figure 16).

The analysis of exonuclease-generated sequence ladders with ESI was shown by Limbach et al.,[160] simplifying the interpretation of the complex mass spectrum by a continuous introduction of the digest solution into the ESI source.

Although gel-based Sanger sequencing can be performed routinely for DNA of up to 500 bp, it can be severely disturbed by gel-band compression or other mobility shifts of the generated fragments. In 1993 Fitzgerald et al.[161] demonstrated that the classical Sanger approach can be adapted for detection by MALDI/MS by analyzing a mixture of synthetic oligonucleotides which mimicked a sequence ladder. These and other similar experiments soon revealed that the removal of template, buffer, salts, and nucleotides prior to the MALDI analysis was crucial.[162,163] This can be achieved by immobilizing the PCR product on solid phases such as streptavidin-coated beads.[83,164] Cycle sequencing is another straightforward approach as the template DNA strand is copied several times by a thermostable DNA polymerase to generate increased amounts of the sequence fragments.[165] Fu et al.[166] reported the sequencing of exons 5 to 8 of the p53 gene (670 bases in total) by primer walking with 21 primers – the nature and site of the polymorphisms of heterozygous DNA templates were elucidated. Taranenko and colleagues[167,168] reported the sequencing of double-stranded templates up to 200 bp with a one-strand-specific primer. Kirpekar et al.[54] analyzed clinical heterozygously expressed samples and demonstrated the superiority of MALDI/MS in exploring the murine PPARδ exon 1 PCR fragment. A 10 bp long part of this fragment was not amenable to gel electrophoresis as a consequence of pronounced band compression and marked nonspecific termination. Figure 17 illustrates the de novo sequencing of this problematic sequence segment.

Figure 17 Generation of de novo sequence information by MADLI/MS product separation. The cycle sequencing was performed on a murine PPARδ, exon 1 PCR fragment. Horizontal arrows show the mass differences used for sequence determination of problematic positions in the sequence. 2P marks the signal of the dimer of the sequencing primer. (Reprinted from F. Kirpekar et al., *Nucleic Acids Res.*, **26**, 2554–2559 (1998) with permission from Oxford University Press, Copyright 1998.)

In this investigation an unexpected nucleotide polymerization event was detected at the third position. Misincorportion of dGMP and also dCMP – clearly seen in the ddC reaction – at this position leads to termination whereas the strong signal in the ddT spectrum reveals the presence of T at this position. False and specific termination can be distinguished from each other as the mass difference of two adjacent signals in the mass spectrum provides information about the type of nucleotide. Doublets (mass difference 16 Da) can be observed in the respective mass spectrum as the incorrect product carries a deoxynucleotide rather than the dideoxynucleotide at the terminus. Further advantages of coupling Sanger sequencing of rather short templates with MS are the ability to obtain sequence information in close proximity to the primer,[168] the high speed of analysis and the ability for automation in process lines. Köster et al. captured biotinylated DNA templates with streptavidin-coated magnetic beads and performed primer extension terminated with the respective ddNTPs in four reactions for sequencing up to 63 nucleotides.[165] Only the primer-extended products are detected as the ionization–desorption process does not disrupt the biotin–streptavidin linkage.[164]

2.5 Clinical Diagnostics with Mass Spectrometry

Clinical diagnostics do not necessarily depend on complete sequencing. Various rapid screening methods for mutations and polymorphisms have been developed which can be easily performed by MS. Multiplexing greatly enhances the amount of information that can be gained in a single measurement. A classical approach to screen for mutations in a given DNA strand is a restriction endonuclease digest followed by gel-electrophoretic separation of the generated fragments, in which differences of the fragment length and/or the pattern are indicators of mutations (restriction fragment length polymorphism RFLP). Lubman and colleagues have adapted restriction endonuclease cleavage of PCR-amplified DNA with subsequent detection by MALDI/MS to screen buccall cell DNA up to 426 bp for polymorphisms.[81,169] The cystic fibrosis gene was the target for Ch'ang et al.[170] who screened the DNA of 30 individuals for the most common ΔF508 deletion using MALDI/MS. Another strategy pursued by this group involves PCR amplification of the DNA of interest (cystic fibrosis transmembrane conductance regulator, CTFR gene) with two pairs of primers, one pair for the wild-type DNA and one pair for the mutant DNA, thus leading to different PCR products for the homozygote wild type, heterozygote, and homozygote mutant patients.[171] Jurinke et al.[172] screened blood bank samples for hepatitis B virus (HBV) DNA by amplifying its encoding core antigen (HBc) with PCR. Biotinylation of one of the primers enabled purification after immobilization on streptavidin-coated magnetic beads and detection of the complementary strand after hybridization with MALDI/MS. The sensitivity was enhanced in following work[173] with the aid of nested PCR, in which HBV DNA was detected in 11 out of 21 sera of patients supposedly cured (positive isolated anti-HBc). The same group reported a rapid screening method for known mutation sites by primer oligo base extension (PROBE) and MALDI/MS.[174] This strategy relies on the annealing of a specific primer, or in a biplex reaction of two primers, downstream of the suspected mutation site and primer extension, in which one of the four deoxynucleotides is completely substituted by its dideoxy analog. Mutations manifest themselves through the length of the PROBE product, and the number of signals are indicators of the heterozygosity of the allele. Performing PROBE as a temperature-cycled rather than an isothermal assay leads to an enhancement in sensitivity.[175] Braun et al.[176] demonstrated that the PROBE reaction is also suited for the analysis of microsatellites by MS if the repeat unit does not consist of all four nucleotides. Investigating the number of AluVpA microsatellite repeat units of the five members of a given family by digestion of the respective PCR product with a restriction endonuclease and subsequent separation by gel electrophoresis showed 13 and 12 repeat units for the mother, 11 and

Figure 18 Comparison of an AluVpA microsatellite analysis using (a) conventional denaturing gel electrophoresis followed by silver staining of DNA fragments and (b) measurements of diagnostic PROBE products (ddGTP termination) by MS. Molecular weight values of primers and extended primers are based on the following nucleotide exact masses: dC, 289.1847; dT, 304.1964; dA, 313.2097; dG, 329.2091; ddC, 273.1898; ddT, 288.2015; ddA, 297.2148; ddG, 313.2142.

Figure 19 Twelvefold multiplex spectrum expanded in three regions, illustrating primer-extended primer pairs (horizontal arrows); $*$ = matrix adduct peaks. The table lists the used genotyping primers for the corresponding polymorphism. (Reprinted from P. Ross et al., *Nat. Biotechnol.*, **16**, 1347–1351 (1998) with permission from Nature America, Copyright 1998.)

8 for the father, and combinations thereof for the three children, whereas the PROBE reaction in combination with MALDI/MS revealed second-site mutations within the 13 repeat unit. It was shown by sequence analysis that transitions of T to C in the second and T to G in the eighth repeat lead to a truncated version of the 13 repeat when the PROBE reaction is performed with ddGTP (Figure 18)

Since its invention PROBE assay has found applications in the analysis of more than 100 mutations/polymorphisms of human genes.[70,177]

Another rapid screening method for the detection of single nucleotide polymorphisms, nucleotide deletion, insertion, and substitution is the pinpoint assay.[178] This approach uses the annealing of specific primers downstream of the putative mutation site/polymorphic region. The analytic information is contained in the mass shift of the single base-extended primer. The assay has a high potential for multiplexing. Figure 19 shows the 12-fold multiplex spectrum of loci listed in the table.

Wunschel et al.[179] used ESI/FTICR analysis for the detection of heterogeneity in the highly conserved 16/23S rDNA interspacing region from *Bacillus cereus* 6464. Interestingly, more PCR-amplified double-strands were detected than expected. The accurate mass measurement of the single-strands revealed a missing T in the coding and a missing A in the noncoding strand, in addition to the predicted masses. Laken et al.[180] analyzed genetic variants of PCR-amplified DNA with ESI ion trap MS coupled to HPLC. The key of this approach, called SOMA (short oligonucleotide mass analysis), is the implantation of an artificial restriction endonuclease type IIS recognition site within the employed primer pair, hence determining the length of the amplified DNA and the length of the digest fragments (7–20 nucleotides) which mirror the genetic variation. The cleavage of the PCR-amplified DNA with restriction endonucleases ensures that the fragment length is amenable for ion trap MS. Figure 20 describes the investigation of common polymorphisms in the APC gene at the codons 485, 545, and 1756.

Figure 20 Simultaneous analysis of three different APC variants for two patients. For each patient, PCR products containing APC codons 486, 545, and 1756 were combined and introduced into the mass spectrometer via the HPLC. The sense (s) and antisense (as) signals are indicated for each genotype. (Reprinted from S.L. Laken et al., *Nat. Biotechnol.*, **16**, 1352–1356 (1998) with permission from Nature America, Copyright 1998.)

The simultaneous detection of the three different codons after combining the separate PCR reactions and digests illustrates the ability to analyze multiplexed reactions. Furthermore, the ion trap can be used to analyze induced fragmentation of the single DNA stretches, providing even more information in cases of isobaric single strands.

Performing diagnostics with MALDI/MS has the advantage that the analysis can be easily combined with computer technology, allowing large-scale diagnostics using parallel processing, whereas ESI is superior when analyzing larger analytes.

2.6 Conclusions

MS is only a recent addition to the plethora of analytical techniques in nucleic acid analysis. Its contributions to the fields of biology, biochemistry, biomedicine, and biotechnology will, no doubt, increase substantially in the near future as new applications and analytical procedures are developed.

ACKNOWLEDGMENTS

We would like to thank Hans C. Lüdemann, Finn Kirpekar and Kerstin Strupat for a critical reading of the manuscript and helpful discussions.

ABBREVIATIONS AND ACRONYMS

A	Adenine
ATT	6-Aza-2-thiothymine
bp	Base Pair
C	Cytosine
CI	Chemical Ionization
CID	Collision-induced Dissociation
DE	Delayed Ion Extraction
dNMP	deoxyribonucleoside 5′ monophosphate
dsDNA	Double-stranded DNA
EI	Electron Impact
EI/MS	Electron Impact Mass Spectrometry
Er/YAG	Erbium/Yttrium–Aluminum–Garnet
ESI	Electrospray Ionization
FAB	Fast Atom Bombardment
FAB/MS	Fast Atom Bombardment/Mass Spectrometry

FD	Field Desorption
FTICR	Fourier Transform Ion Cyclotron Resonance
FTICR/MS	Fourier Transform Ion Cyclotron Resonance Mass Spectrometry
FWHM	Full-width at Half-maximum
G	Guanine
HBV	Hepatitis B Virus
HPLC	High-performance Liquid Chromatography
ISD	In-source Decay
IR	Infrared
IRMPD	Infrared Multiphoton Dissociation
MALDI	Matrix-assisted Laser Desorption Ionization
MALDI/MS	Matrix-assisted Laser Desorption Ionization/Mass Spectrometry
MS	Mass Spectrometry
NC	Nitrocellulose
Nd/YAG	Neodymium/Yttrium–Aluminum–Garnet
NS	Nozzle Skimmer
PA	Picolinic Acid
PCR	Polymerase Chain Reaction
PD	Plasma Desorption
PROBE	Primer Oligo Base Extension
PSD	Post-source Decay
RFLP	Restriction Fragment Length Polymorphism
RPHPLC	Reversed-phase High-performance Liquid Chromatography
SI	Secondary Ion
SIMS	Secondary Ion Mass Spectrometry
SOMA	Short Oligonucleotide Mass Analysis
ssDNA	Single-stranded DNA
T	Thymine
TIC	Total Ion Current
TOF	Time-of-flight
THAP	Trihydroxyacetophenone
Tris	Tris(hydroxymethyl)aminomethane
U	Uracil
UV	Ultraviolet
3-HPA	3-Hydroxypicolinic Acid

Nuclear magnetic resonance (NMR) is one of the most important and widely used techniques for studying nucleic acid structure. With modern techniques, including isotope labeling and multidimensional spectroscopy, structures of large molecules – nucleic acids alone or in complexes, for example with proteins or ligands – can be determined. Here is given an overview of experimental NMR methods for nucleic acids studies, complemented by illustrative examples of DNA, RNA and PNA structures.

1 INTRODUCTION

NMR is one of the most important and widely used techniques for studying nucleic acid structure. NMR offers the advantage of permitting high-resolution studies of molecules in solution, and thus of manipulating conditions such as concentration of various ions and ligands, temperature and pH. Although the number of NMR spectra of nucleic acids acquired in solid phase is growing rapidly, the vast majority of experiments are still carried out in aqueous solution. This review will therefore focus on nucleic acid structure in solution as studied by NMR methods. This subject has previously been carefully reviewed, for example by Van de Ven and Hilbers[1] and by Patel et al.[2]

There has been a hand-in-hand development of increasingly more affordable methods of preparing isotope-labeled oligonucleotides, both DNA and RNA, and new pulse sequences taking advantage of their incorporation. Many of these pulse sequences are tailored to detect single correlation pathways that are instrumental in making correct assignments of a spectrum. To cover an inclusive menu of experiments now available would be formidable, task, such a list could not be condensed into the format of this article, and even if it could, would quickly become outdated. The aim here is instead to give a general introduction to available techniques complemented by illustrative examples of a few representative structures. These structures should give an idea of the range of problems now tractable by NMR and indicate strategies for solving them.

2 NUCLEAR MAGNETIC RESONANCE AND NUCLEIC ACIDS

Nucleic acids are structurally versatile molecules (for detailed descriptions of nucleic acids nomenclature and parameterization, please refer to Saenger[3] and Lu and Olson[4]). With DNA this is manifested as a multitude of tertiary structure motifs seen primarily as a variety of multistranded complexes. RNA is also highly variable at a secondary structure level, with alternate basepairing interactions and intricate folding topologies. For structural information about nucleic acids to be meaningful, a high degree of accuracy is therefore required and structural information derived from NMR experiments will often not be conclusive unless the spectra of a molecule can be unambiguously interpreted. Techniques have been developed that have considerably widened the scope of NMR studies. In particular, improved and more affordable isotope-labeling methods combined with higher field instrumentation and multidimensional pulse sequences have permitted structure studies of nucleic acids as long as 40 nucleotides, even in complexes with proteins, possible by NMR.[5]

2.1 Spectral Properties

2.1.1 DNA

The proton NMR spectrum of DNA (Figure 1) is usually nicely distributed between 0 and 15 ppm. For molecules with a relatively low degree of complexity, such as a duplex, it is often possible to carry out assignments

Figure 1 Schematic structure of PNA, DNA and RNA. b = base.

unambiguously for the majority of the protons in an unlabeled sample based solely on two-dimensional (2D) experiments. Typical proton spectra of a DNA duplex in D_2O and H_2O are shown in Figure 2. Protons that do not exchange at a significant rate with the solvent generally appear in the region between 0.5 and 8.5 ppm (Figure 2a). Labile protons, such as the amino and imino protons are usually observed between 6–10 ppm and 11–15 ppm, respectively (Figure 2b).

Figure 2 One-dimensional proton spectrum of the self-complementary DNA duplex $[d(CGCGATCGCG)]_2$ in D_2O solution at 38 °C (a), and in H_2O solution at 10 °C (b).

Assignment of the nonexchangeable protons – the aromatic H6/H8, H2, H5 and the methyl and sugar protons of a regular B-form DNA duplex – can usually be done from NOESY (nuclear Overhauser spectroscopy) and COSY (correlation spectroscopy) data recorded in D_2O, while the exchangeable protons can be assigned from H_2O NOESY spectra. Sometimes data acquired at a few different temperatures are helpful in overcoming assignment problems caused by spectral overlap.

2.1.2 RNA

In ribonucleotides the 2′-hydroxy group (Figure 1) causes the H2′ resonances to shift downfield so that they overlap with the H3′ signals. The H5 resonances of the uracil bases appear in the 5.0–6.0 ppm region along with their cytosine analogs. Because of overlap in the sugar proton region, complete assignment of an RNA oligonucleotide may be difficult without the use of isotope labeling and a number of multidimensional experiments. Strategies for this are described in more detail in section 2.2 below.

2.1.3 PNA

The nucleobases in PNA (peptide nucleic acid, Figure 1) are the same as in DNA and RNA, and their spectral features are thus similar. The chemical shifts of the aromatic protons tend to appear slightly upfield of the corresponding DNA resonances (Figure 3).[6] Each residue of the PNA backbone (*N*-(2-aminoethyl)-glycine) contains four pairs of nonexchangeable methylene protons and one exchangeable amide proton. Owing to the different environments of the methylene pairs in PNA, assignments of these can generally be carried out, but stereospecific discrimination cannot be performed unambiguously without specific labeling. Basepairing of a PNA strand to DNA of a complementary sequence results in the formation of a stable hybrid complex that exhibits an NMR spectrum that differs both from the PNA and DNA single strand spectra. A representative spectrum of a PNA strand hybridized to DNA is shown in Figure 3.

2.2 Techniques Used

Nucleic acids of biological significance are often, even as model systems, large enough to pose technical challenges when studied by NMR. Whereas small molecules of DNA are usually tractable solely using their proton resonances, NMR studies of RNA and larger or more complex DNA molecules would be prohibitively difficult without the use of additional paramagnetic nuclei, typically ^{13}C and ^{15}N, as labels. Important progress has been made in techniques for producing isotope-labeled DNA and RNA molecules. In addition, partial deuteration of large molecules can be

Figure 3 One-dimensional proton spectra of PNA strand H-GCTATGTC-NH_2 (a), DNA strand d(GACATAGC) (b) and the 1:1 PNA:DNA duplex H-GCTATGTC-NH_2·d(GACATAGC) (c) in D_2O solution at 24 °C.

used to alleviate a number of problems associated with large molecules in NMR experiments.

2.2.1 Isotope Labeling and Sample Preparation

2.2.1.1 RNA Labeling of RNA oligonucleotides with the NMR active isotopes ^{13}C and ^{15}N is efficiently done by enzymatic synthesis in vitro. Isotope-enriched nucleotide 5′-triphosphates (NTPs) can be prepared by growing bacterial cells in glucose–mineral salt containing the chosen isotope labels – typically *E. coli* cells are grown in ^{13}C glucose and ^{15}N ammonium sulfate.[7] Alternatively, ^{13}C methanol may serve as a less costly source of ^{13}C.[8] After isolation, the nucleic acid chains are degraded to mononucleotides by nuclease treatment. The RNA monomers are separated from DNA and enzymatically phosphorylated to NTPs. The labeled NTPs can then be used as substrate for in vitro transcription using a synthetic DNA template, typically using T7 polymerase, of RNA molecules of the desired length and sequence. Unincorporated nucleotides can be recovered and reused. The procedure can yield milligram quantities of labeled RNA for NMR experiments. Methods describing base selective isotope enrichment of RNA by residue type and the incorporation of these into large RNA fragments have also been reported.[9]

2.2.1.2 DNA A number of strategies have been demonstrated to produce high yields of labeled deoxyribonucleotides at low cost.[10] Today there are several strategies that provide uniformly ^{13}C and ^{15}N labeled DNA oligonucleotides by enzymatic synthesis.[11–13] Deoxynucleotides can be obtained from bacteria grown on ^{13}C and ^{15}N enriched nutrients, isolated and enzymatically phosphorylated to dNTPs. These can be used as building blocks in a polymerase chain reaction (PCR) using a DNA template and a DNA primer carrying a 3′-terminal ribonucleotide. The single 2′OH acts as a substrate for alkaline hydrolysis, which is used to cleave the product strand to be separated from the primer.

Labeled DNA oligomers can be made by cloning multiple copies of the desired oligonucleotide flanked by restriction sites into a plasmid which is transformed into bacteria that are grown with $^{15}NH_4Cl$ as nitrogen source. The use of ^{13}C for this purpose is at present excessively costly. Cleavage of the isolated plasmid DNA gives labeled oligonucleotides, with starting material for labeled dNTPs as a side product. Alternatively, endonuclease sensitive repeat amplification, or ESRA, can be performed by running many cycles of PCR to produce very large amounts of DNA fragments that will be ^{13}C and ^{15}N labeled if isotope enriched dNTPs are used. Procedures for site specific[14] and region specific incorporation of labeled DNA oligonucleotides[15] have been described as well. These particularly enable highlighting of portions of large DNA molecules or protein–DNA complexes that are of special interest.

2.2.1.3 Partial Deuteration Selective deuteration of oligonucleotides may be introduced in order to suppress part or parts of the proton spectrum. Conditions for efficient deuteration have been worked out for the exchange of pyrimidine H5/H6 and purine H8 protons, and applied to simplify the assignment of homologous DNA repeat sequences.[16] Synthesis protocols for incorporating deuterons stereospecifically in the 2′, 3′, 4′, 5′ and 5″ positions in RNA and DNA have been reported.[17,18] Aside from reduced spectral crowding, the advantages of partial deuteration of oligonucleotides include improved resolution and sensitivity. These effects are mainly due to the fact that both the T_1 and T_2 relaxation times of nuclei vicinal to the deuterons increase considerably.[18,19]

It is desirable that NMR samples of macromolecules (such as nucleic acids) are pure. In the case of nucleic

acids it is therefore necessary to include a purification step in the sample preparation in which the desired molecules are separated from fragments of similar size. The most common method for such purification is HPLC (high-performance liquid chromatography) on a reverse-phase column. This is typically followed by exchange of solvent and counter ions on an ion-exchange column or by dialysis.

2.2.2 *Experiments*

For structure studies of nucleic acids by NMR, the experiments can be divided into three stages. First, one-dimensional spectra are recorded. These are useful for indicating sample purity (both with respect to chemical and conformational composition), sensitivity to pH and temperature, and characteristics such as spectral distribution and the general quality of the spectrum and feasibility of further studies. In addition, the presence of stable basepairs or hydrogen bonds can be seen from one-dimensional spectra. Furthermore, titration with proteins or other ligands is monitored as changes in a one-dimensional spectrum. Second, various multidimensional experiments are recorded in order to establish assignments of as many as possible of the NMR active nuclei in the molecule. Stage three consists of recording quantitative measurements of structural parameters such as internuclear distances (NOE, nuclear Overhauser effect volumes) or dihedral angles (coupling constants) that can be used for structure determination.

In studying nucleic acids in aqueous solution by NMR one has to distinguish between spectra recorded in H_2O and D_2O solution. In H_2O solution all protons are visible (including solvent water), whereas in deuterated solvents only the protons that are covalently attached to the molecule can be detected beside the residual water peak. Because in nucleic acids the labile amino and imino protons generally exchange rapidly and appear mostly downfield of the stable ones, the spectral width of a D_2O experiment can often be kept relatively small, allowing for higher resolution without increasing the amount of data recorded. Disregarding the labile proton resonances, which often require low temperatures (below 10 °C) for stabilization and detection, permits spectra in D_2O solution to be recorded at the higher temperatures at which the peak widths tend to be smaller.

There are two particular types of effect that can be measured quantitatively from NMR data – coupling constants and interatom distances. Different varieties of the 2D COSY and NOESY experiments are primarily used for these purposes, respectively. In a COSY spectrum, crosspeaks that show splitting patterns contain information about dihedral angles between protons separated by no more than three bonds. The relation between the coupling constant J, measured as the splitting observed within one crosspeak in a phase-sensitive COSY spectrum, typically measured in Hertz, can be expressed by the semiempirical Karplus equation, Equation (1)

$$^3J = A\cos^2(\phi) + B\cos(\phi) + C \qquad (1)$$

The constants A, B, and C can be determined from measurements of ^3J in molecules with known values of the angle ϕ. Fitting of measured angular data, for example between the protons in a ribose sugar, has been worked out extensively (see Wüthrich[20] and Rinkel and Altona[21]). In a NOESY spectrum of a molecule the size of an oligonucleotide, the crosspeak buildup rate, μ_{ij}, measured as its integrated volume versus mixing time, is related to the interatom distance of the resonances involved, r_{ij}, as, Equation (2)

$$r_{ij} = c\mu_{ij}^{1/6} \qquad (2)$$

where c is a constant that can be determined from a crosspeak representing two covalently connected protons of known separation (e.g. H5–H6 of cytosine or uracil of 2.45 Å, or the intrasugar H2′–H2″ distance of 1.85 Å).

Small molecules with a regular conformation, such as double-stranded DNA oligonucleotides or short RNA stems, can often be successfully approached by homonuclear 2D NOESY and COSY experiments, relying on the regular helical conformation for which sequential assignment strategies are relatively straightforward.[2,20]

Sequential assignment of duplex DNA in a B-like conformation[3] is most easily performed in the aromatic–H1′ region of the NOESY spectrum which is characterized by intraresidue and sequential crosspeaks of similar intensity. Knowledge of the nucleotide sequence and the expected approximate chemical shifts of the different bases usually suffices to find a trace along the stack of residues. Good markers are the strong intraresidue crosspeaks arising from H5–H6 interactions in cytosines, seen in COSY as well as NOESY spectra. Strong intraresidue NOESY crosspeaks are also seen from the thymine H6–methyl interactions. These markers are helpful in identifying the H6 of DNA pyrimidines and their 5′ flanking residues. Alternating inter- and intraresidue crosspeaks between H6/H8 and H1′ protons (Figure 4) can typically be connected to a trace in the aromatic–H1′ region of a NOESY spectrum. A similar sequential trace can also be followed between the aromatic–H2′ and H2″ protons crosspeaks where the intraresidue H6/H8–H2″ interactions tend to be stronger and resonate slightly downfield compared with the corresponding H2′ protons. Furthermore, the H3′ and H4′ resonances may sometimes be assigned in

Figure 4 Schematic illustration of intra- and interresidue dipolar NOE interactions observable in a B-form DNA strand.

the same manner, although weaker sequential interactions and more extensive overlaps often make this more difficult, and additional spectral regions usually need to be analyzed for conclusive assignment of the H3′ and H4′ protons. Once tentative assignments of the H1′, H2′ and H2″ resonances have been made, these can be crosschecked by identifying the intraresidual cross-peaks in the H1′–H2′ and H1′–H2″ regions of NOESY and COSY spectra. The H2 protons of adenine bases can be distinguished from other aromatic resonances by their characteristically long spin–lattice relaxation times, which can be detected through inversion recovery experiments.[22]

As for the exchangeable protons, the amino resonances show strong NOEs to the H5 and H6 resonances on the same residue. The thymine imino resonances are most easily identified from their strong interactions with the H2 protons of their respective basepaired adenines. The guanine imino protons show strong NOE interactions with the amino protons of their respective basepaired cytosines. The imino resonances often exhibit sequential imino–imino NOE connectivities among themselves that can be readily traced. However, the imino protons of the terminal basepairs usually exchange too rapidly to be detected under normal experimental conditions.

The assignment of larger molecules that give rise to overcrowded spectra and of molecules of unknown secondary structure, for which sequential assignment strategies break down, requires combination of isotope-labeled samples and various 2D and 3D (three-dimensional) experiments. This need is particularly pronounced for RNA, where overlap in the sugar region is severe and the H1′ and H2′ coupling is very weak (<3 Hz) in the C3′-*endo* conformation which generally predominates in RNA sugars. Whereas in a 2D experiment, interactions involving two specific nuclei can be resolved, in a 3D spectrum the involvement of a third nucleus in the magnetization transfer pathway can be visualized. This not only adds resolution along the third dimension, but also offers the possibility of 'filtering' the magnetization transfer through a chosen type of nucleus.

When assigning an RNA molecule HMQC (homonuclear multiple quantum correlation spectroscopy) and HSQC (homonuclear single quantum correlation spectroscopy) experiments are useful for classification of nonexchangeable proton resonances through $^{1}H-^{13}C$ and $^{1}H-^{15}N$ correlations. Ribose protons can be efficiently assigned by a set of 3D correlation experiments as described by Pardi.[23] Assignment of all protons in a ribose spin system of a ^{13}C-labeled sample can be accomplished by performing a set of HCCH–COSY, HCCH–RELAY and HCCH–TOCSY (total correlation spectroscopy) experiments.[24] The individual ribose spin systems can then be connected by $H_sC_sN_bC_bH_b$ triple-resonance experiments (s and b refer to sugar and base, respectively) (Figure 5a).[25,26] A method for sequential through-bond correlation of ^{13}C-labeled nucleotides has been described,[27] and through a ^{1}H, ^{13}C, ^{31}P triple-resonance experiment (HCP-CCH-TOCSY) correlation of all ribose protons on both the 5′-side and 3′-side of a backbone phosphate nucleus can be made (Figure 5b). In addition to these experiments, usage of partial deuteration and selectively incorporated isotope labels may increase the resolution and sensitivity as discussed above.

Correlation of the exchangeable amino and imino protons in fully ^{13}C and ^{15}N labeled RNA can be done

Figure 5 Schematic representation of coherence transfer pathways connecting base and sugar in the HCNCH experiment, indicated in bold gray (a), along the backbone in the HCP-CCH-TOCSY experiment (b), and within the guanine, adenine and uracil bases in the HCCNH-TOCSY experiment (c).

using HCC(C)NH-TOCSY experiments that are well suited to assigning exchangeable protons in nonregular portions of structures (Figure 5c).[28,29–31] To assign DNA structures containing ^{13}C and ^{15}N labels strategies that use the same NMR experiments that are used for the assignment of RNA molecules can be applied.

Following successful assignment of the resonances in a molecule, experiments tailored to generate structure information can be conducted. For internuclear distance measurements, various types of NOESY experiments, such as 3D NOESY/HMQC[32] and four-dimensional HMQC/NOESY/HMQC[7,32] may be used. In addition to homonuclear 2D NOESY spectra, from which interproton distances can be estimated with reasonable accuracy, heteronuclear 3D experiments may be a useful source of distance constraints, particularly for large molecules in which spectral overlap may prohibit the measurement of individual 2D crosspeak intensities.

The use of dihedral angles (derived from *J*-couplings) in the structure determination of nucleic acids can be of crucial importance, particularly for determining conformations of the backbone where dipolar proton interactions (NOESY crosspeaks) are sparse or difficult to resolve. For unlabeled molecules the determination of sugar conformations from *J*-coupling data has been described by graphical[21] and simulation[33] methods. For ^{13}C-labeled nucleic acids, special experiments have been developed to determine a complete set of coupling constants for oligonucleotides.[34] A novel method for quantitative measurements of the three-bond $^{1}H3'-^{31}P$ couplings in nucleic acids and nucleic acid–protein complexes based on constant time COSY experiments has been reported.[35]

The pioneering technique of measuring dipolar coupling in samples partially oriented by anisotropic cosolutes[36] has been applied to nucleic acids.[37] The cosolute, in this case filamentous phage, becomes aligned in the magnetic field, which is sufficient to extract net through-space $^{1}H-^{15}N$ dipolar coupling. Double quantum filtered (DQF) COSY experiments carried out with the addition of phage not only have the potential to give a large number of angular constraints that complement distance and *J*-coupling derived dihedral angle constraints, but also to yield long-range angular information of a type that has not previously been accessible using standard NMR techniques.

Biological molecules in solution always undergo dynamics on different timescales. Perhaps the most well-characterized motion in nucleic acids is the basepair opening dynamics. Imino protons in Watson–Crick basepairs are usually well resolved and thus can, after assignment, report on hydrogen bonding events specific to individual basepairs. The guanine H1 and thymine H3 protons, located in the center of the basepair, are only accessible to exchange after transient opening and lateral motion of one or both of the bases. Amino protons on basepaired cytosines rotate much less frequently than non-base-paired amino protons, resulting in the appearance of well-resolved resonances from hydrogen bonded and exposed protons at characteristic chemical shift intervals (8.0–8.5 ppm and 6.5–7.0 ppm, respectively). Amino protons of adenines and guanines, on the other hand, rotate at intermediate rates and give rise to broad peaks that are often difficult to detect. The exchange of imino protons is catalyzed by base.[38] When paired and open states are in rapid equilibrium the imino protons exchange occasionally and at a measurable rate, τ_{ex}, that depends on the concentration of catalyst [B] and can be expressed according to,[2] Equation (3)

$$\tau_{ex} = \tau_0 \left(\frac{1 + B_{eq}}{[B]} \right. \tag{3}$$

where B_{eq} is the buffer concentration at which $k_{cl} = k_{tr}$, i.e. the closing rate is equal to the proton transfer rate, and can be estimated from the base concentration for which $\tau_{ex} = 2\tau_0$. Extrapolation to infinite buffer concentration gives the basepair lifetime, τ_0. The exchange rate is most commonly measured as $\tau_{ex} = (\pi\Delta\nu)^{-1}$, where $\Delta\nu$ is the line width at half height of the resonance of interest. From studies of imino proton exchange it has become clear that the basepair opening rates are sequence dependent. For example, the exchange times of guanine iminos in G_n tracts are shorter (less than 5 ms) than in $(GC)_n$ tracts or isolated GC basepairs. In contrast the lifetimes of thymine iminos in AT tracts are very long.[39]

Water molecules have an important role in stabilizing nucleic acid structures. This role is partly played by specific association of water molecules to the surface of nucleic acid molecules. Detection of such bound water and estimation of residence times can be done by NMR techniques.[40,41] Interactions between water and nucleic acid protons, for example in one of the grooves of B-form DNA, can be seen as crosspeaks in a NOESY spectrum. Owing to efficient exchange of water molecules between the hydration sites and the bulk, all water peaks appear along the chemical shift of the bulk water signal. It is necessary to differentiate between crosspeaks arising from chemical exchange of water molecules, on the one hand, and exchange NOE crosspeaks arising from nonexchangeable DNA protons and labile DNA protons that exchange rapidly, on the other hand. If the nonexchangeable DNA proton of interest is located close to potentially labile DNA protons, these may appear as slowly exchanging water molecules visible at the chemical shift of bulk water, although they cannot be distinguished from DNA protons in rapid exchange with solvent. DNA protons that exchange rapidly give rise to crosspeaks with the water signal that are positive in a NOESY (NOE

spectroscopy in the rotating frame) and positive in a ROESY (nuclear Overhauser enhancement spectroscopy in the rotating frame). True water–DNA NOEs, in contrast, will give rise to negative ROESY crosspeaks.

Basepairing through hydrogen bonds primarily manifests itself as imino proton resonances, visible because of the slowed down imino proton exchange. In a reported experiment direct evidence of basepairing hydrogen bonds has been observed. In a J_{NN} COSY experiment of ^{15}N-labeled RNA two-bond couplings between the N1 of adenosine and the N3 of uracil and between the N1 of guanine and the N3 of cytosine, couplings of approximately 7 Hz have been measured.[42] Further experimental development has also made possible the observation of J_{NN} coupling between ^{15}N nuclei with large chemical shift separations, as shown between amino and N7 nuclei in a uniformly ^{15}N-labeled DNA molecule.[43]

2.2.3 Refinement

Completing a macromolecular structure based on NMR data in practice requires computational modeling into which experimental constraints consisting of internuclear distances and/or dihedral angles can be incorporated. It is generally agreed that the most efficient way of arriving at a molecular structure that satisfies all experimentally derived constraints is to generate a number of starting structures by embedding the molecule according to distance data using so-called distance geometry.[44] Thereafter, molecular dynamics calculations using one of the available forcefields are carried out, typically using a simulated annealing protocol to refine the structure.[44] Incorporation of any adduct or complex into the structure should be done at the structure generation stage. For molecules that can be anticipated to be close to a known conformation, suitable starting structures can be built, for example canonical B-form DNA. However, one has to verify that the final product does not suffer from being biased by the choice of starting conformation. If the structure relies heavily on interproton distance data and high accuracy, for example regarding sugar pucker conformation, it may be appropriate to include relaxation matrix refinement in the molecular dynamics protocol to account for spin diffusion effects adequately, as discussed below.

Care should be taken to ensure that chirality errors do not occur as a result of refinement processes, which has been observed to happen in numerous reported nucleic acid structures.[45]

2.3 Critical Comments

2.3.1 Accuracy and Validity

Several factors limit how accurately nucleic acid structures can be determined by NMR methods. In solution nucleic acids are not static molecules that adopt structures that can be characterized with infinite accuracy. Rather, RNA and DNA constantly undergo dynamic processes that should be taken into account when describing an RNA or a DNA solution structure. Since NOE intensities do not scale linearly with internuclear distances, it is often not possible to satisfy consistently all NOESY-derived distance constraints and angular constraints within one structure, even if a two-state model with alternate sugar conformations is assumed. However, from analysis of the NOE intensities in a spectrum of a duplex DNA it has been concluded that restricted rotational diffusion around the glycosidic bond, χ, combined with sugar repuckering can explain the observed spectral features satisfactorily.[46] Furthermore, from relaxation studies of ^{13}C-labeled purines in a duplex it has been found that in addition to overall isotropic tumbling, which occurs on the timescale of 3–4 ns, there is fast (20 ± 20 ps) internal motion of individual purines. This motion, if described as wobble-in-a-cone, is restricted to $\pm 22.5°$ for the 1′, 3′, 4′, 2 and 8 protons in the purine, with no apparent sequence dependence.[47]

2.3.2 Potential and Limitations

The effects of spin diffusion give rise to significant errors in NOE-derived internuclear distance measurements, particularly when long NOESY mixing times (>100 ms) are employed.[48] Experimental methods to overcome this through network editing techniques have been developed. In BDNOESY (band decoupled nuclear Overhauser spectroscopy)[49] and CBDNOESY (complementary band decoupled nuclear Overhauser spectroscopy)[50] experiments, pulses are applied during the mixing time that effectively suppress the effects of spin diffusion through non-H1′ ribose protons and all intraribose cross-relaxations, respectively. The resulting data allow tighter error limits during refinement which give improved precision and allow longer mixing times, thereby giving higher sensitivity and increasing the maximum distance that interactions can be detected. This method has been demonstrated on a ribozyme structure.[50]

It has been concluded that RNA molecules as large as 15 kDa should be amenable to structure determination by NMR methods with a precision and accuracy of 1–1.5 Å.[51] It is also noted that the most substantial improvements in structure quality were accomplished by including constraints derived from exchangeable protons rather than using narrower distance constraints. The molecular size limit is to a large degree set by the availability of experimental constraints – internuclear distances and dihedral angles. The number of constraints per residue is more likely to be large in molecules with

globular shapes, such as compactly folded RNAs. Thus, with instruments of higher sensitivity and with efficient labeling techniques and more robust refinement methods the future appears promising for structure studies of molecules of increasing size.

3 STRUCTURES DETERMINED

3.1 DNA Motifs

3.1.1 Duplex Structures

Among the many solution structures of DNA oligomers that have been determined by NMR methods, the structure of the TATA-box containing self-complementary octamer d(GGTATACC) will be discussed first.[48] The final structures of the octamer duplex were based solely on interproton distance constraints, with the effects of spin diffusion accounted for by inclusion of relaxation matrix calculations in the refinement protocol. The use of a 3D proton NOESY–NOESY experiment (120 ms mixing time in both indirect dimensions) clearly illustrated spin-diffusion pathways as crosspeaks appearing at chemical shifts that were different in all three dimensions. For example intraresidue H6 → H2′ → H3′ and H6 → H2″ → H1′ crosspeaks were seen, demonstrating that the H2′ and H2″ protons mediate spin diffusion efficiently. Similar diffusion pathways were also seen in sequential aromatic–sugar interactions. From the resulting structures it was concluded that the molecule in solution adopts a structure that relatively closely approximates the canonical B-conformation.

DNA displays structural irregularities – sequence and condition-dependent features that may be crucial to its biological function. A molecular structure of extended shape, such as a DNA duplex, determined from short-range distance constraints, has an intrinsic lack of accuracy attached to it. It should thus be pointed out here that the structural details that may be sought in a high-resolution structure of an oligonucleotide duplex alone in solution need to be most carefully established in order to merit significant conclusions to be based upon them.

3.1.2 Triplex Structures

DNA of appropriate sequences under favorable conditions will form three-stranded complexes. A number of different triplet basepairing schemes have been observed, as reviewed by Radhakrishnan and Patel.[52] The most commonly encountered triplex is based on the pyrimidine·purine–pyrimidine motif. In this complex, the Watson–Crick pairing pyrimidine-rich strand runs antiparallel to the purine-rich strand to which the second pyrimidine strand binds in a parallel alignment through Hoogsteen hydrogen bonds (Figure 6).

Figure 6 Alignment of bases in base triplets: C^+·G-C (a), T·A-T (b) and G·T-A (c).

The hydrogen bonds predicted for this motif were confirmed by NMR studies focusing on exchangeable resonances and strand orientation.[53,54] Stable formation of such triplexes requires protonation of the cytosines on the Hoogsteen strand, and is thus favored by low pH. The one-dimensional proton NMR spectrum of a unimolecular DNA triplex that includes a G·T-A triplet in the center is shown in Figure 7.

A few notable features will be pointed out. First, the cytosine imino protons appear downfield of the other imino proton peaks (14.5–16.0 ppm). Downfield shifting of the exchangeable as well as nonexchangeable protons in the protonated cytosine generally follows upon protonation. Second, the thymine iminos

Figure 7 Proton spectrum, 5.5–15.5 ppm (a), with expanded imino proton region (b) of the triplex forming DNA sequence (c). (Reproduced by permission of Radhakrishnan et al., *Biochemistry*, 1991.[55] American Chemical Society.)

on the Hoogsteen strand resonate somewhat upfield (12.8–13.9 ppm) of the Watson–Crick thymine imino resonances (13.8–14.6 ppm). Third, both of the adenine amino protons are engaged in hydrogen bonding and appear in the 8.0–8.5 ppm region, whereas the hydrogen-bonded amino resonances of the protonated cytosine appear between 8.5 and 10.0 ppm. The spectrum of exchangeable protons is thus mostly well resolved, the imino resonances of the thymine loops seen around 11 ppm being an exception. The imino and amino protons in the Watson and Crick strands in this sequence were assigned by strategies similar to those described for a regular duplex (section 2.2 above) using 2D NOESY spectra recorded in H_2O solution with intermediate mixing times (120 ms).[54] In addition NOESY crosspeaks between thymine imino protons in T·A-T triplets and hydrogen bonded adenine amino protons are observed. The Hoogsteen pairing imino protons in the T·A-T triplets show NOEs to the H8 of the adenine and to the hydrogen-bonded adenine amino proton. The H8 of all adenines and guanines can be selectively deuterated in order to aid the identification of some of the imino crosspeaks. For the C^+·G-C triplet, strong NOEs are seen between the hydrogen-bonded and exposed amino protons on the protonated cytosine Hoogsteen-bound to the guanine.

The nonexchangeable protons of the molecule were assigned from a 3D NOESY/TOCSY experiment.[56] In this experiment the first step is a dipolar interaction NOE, whereas the second step involves a coherent transfer of magnetization between scalar coupled spin pairs. The experiment facilitated identification, for example of the various protons showing NOE interactions with H2′ and H2″ protons, which in turn exhibit strong couplings with the well-resolved H1′ resonances. The 3D structure of the triplex (sequence in Figure 7) is shown in Figure 8. The triplex was allowed to form in solution with Li^+ as counterions to avoid formation of four-stranded complexes which may be favored in G-rich sequences with Na^+ or K^+ present. The Watson–Crick paired strands do not deviate substantially from a regular duplex conformation, although some basepair displacement and helical unwinding is seen. The glycosidic angles are all in the *anti* domain and all sugars are in the S conformation, except for the guanine of the G·T-A triplet, which adopts the N

Figure 8 Stereo view of DNA triplex containing a G·T-A triplet, loops excluded. Strand I corresponds to bases C1–C7, strand II to G8–G14 and strand III to C15–C21 in the sequence shown in Figure 7. The strands are labeled at their 5′ ends. (Reproduced by permission of Dr. D.J. Patel of Sloan-Kettering Institute, New York.)

conformation. While the base triples are generally planar, the guanine of the G·T-A is tilted towards the 3′ direction. The grooves are all different, with the Watson–Crick groove being slightly narrower than in a duplex with a fairly smooth surface. The Watson–Hoogsteen groove in contrast appears largely wide, shallow and uneven. The Crick–Hoogsteen groove is narrow and has distinct cavities on its surface. Considering its lining of polar residues, this groove provides potential binding sites for water or positively charged ions. Ordered water molecules in the Crick–Hoogsteen groove have indeed been found, as shown from a combination of homonuclear NOESY and ROESY experiments carried out on the same triplex molecule.[57] Similarly, in the Watson–Hoogsteen groove, water molecules with residence times longer than 1 ns were found. The water molecules in the Watson–Crick groove of this triplex were found to be more mobile, in contrast to the spine of hydration found in the minor groove of duplex DNA.[41]

3.1.3 Quadruplex Structures

Four-stranded DNA complexes have received much attention, partly owing to their potential relevance to telomere sequences (guanine-rich multiply repeated short sequences at the ends of chromosomes). Understanding the structure and topology of these repeat sequences may lead to functional insights of biological or medical importance. Several types of intra- and intermolecular quadruplexes with different types of pairing alignments and combinations of strand directionalities have been studied (reviewed by Rhodes and Giraldo[58] and Darlow and Leach[59]). Both NMR and X-ray crystallography methods have been employed to determine structures of DNA quadruplexes.

Generally, G quartets (Figure 9) are highly stable, as has been evidenced, for example, by NMR studies of the human telomere sequence. Upon change of solvent from H_2O to D_2O the exchange of the imino protons with deuterons occurred at remarkably low rates that could be followed over days in the NMR spectrum.[60]

Figure 9 Alignment of guanine bases in G tetrad.

Figure 10 Topology of quadruplex structure formed by d($G_1G_2G_3C_4T_5T_6T_7T_8G_9G_{10}G_{11}C_{12}$).

Quadruplexes generally require the presence of low concentrations of monovalent cations for their stability, often discriminating between different types of ions. Typically potassium and sodium ions are found to coordinate the arrangement of bases in and between the tetrads, whereas lithium ions are too small to fulfill this function.

As an example of a four-stranded complex the structure formed by GGGC repeats, found in adeno-associated viral DNA, will be discussed.[61] In addition to forming G-tetrads this structure also forms G·C·G·C quartets (Figure 10). The four strands, combined by head-to-tail dimerization of two hairpins, run antiparallel to each other around the quadruplex, with lateral T_4 loops connecting the pair of arms on each hairpin. The interaction between the two intrastrand Watson–Crick GC basepairs is mediated by bifurcated Hoogsteen hydrogen bonds involving the major groove edges of the bases. In guanine tetrads the *syn* conformation around the glycosidic bond is commonly observed. In the present example the guanines of the G2 and G10 in the G·G·G·G·G tetrads are in the *syn* form, while the remainder of the bases are in the *anti* conformation.

The spectrum of this sequence (Figure 11a) in H_2O solution containing sodium ions shows two resonances between 13.0 and 13.4 ppm, characteristic of Watson–Crick interactions, and four additional peaks between 11.1 and 12.0 ppm, characteristic of G_4 tetrad formation.[62] The number of peaks seen in the spectrum shows that any four stranded complex formed must possess two-fold symmetry. All four cytosine amino protons of one symmetric unit are seen in the 8.7–9.4 ppm region, indicating that they all are engaged in hydrogen bonding.

Unambiguous assignment of the guanine imino proton resonances was reached through site-specific

Figure 11 Proton spectra of d($G_1G_2G_3C_4T_5T_6T_7T_8G_9G_{10}$-$G_{11}C_{12}$) in H_2O solution at 10 °C stabilized by 100-mM Na^+ (a), and 100-mM K^+ (b). (Reproduced by permission of Bouaziz et al., *J. Mol. Biol.*, (1998) Academic Press.[63])

incorporation of ^{15}N isotopes in the N1, N2 and N7 positions of bases G1 and G10. Differences in the proton spectral pattern between ^{15}N decoupled and ^{15}N undecoupled spectra then enabled identification of the G1 and G10 imino proton resonances, which in turn permitted the assignment of the remaining imino protons of the molecule through analysis of NOESY spectra. The involvement of the G1 and G9 imino protons in G-C Watson–Crick base pairing was concluded from their showing NOEs to cytosine amino and H5 protons on the opposing base. Each of the G2, G3, G10 and G11 imino protons exhibits an NOE to the guanine H8 proton in the Hoogsteen aligned position. In the nonexchangeable proton NOESY spectrum strong intraresidue crosspeaks between H1′ and H8 are seen for G2 and G10 at short mixing times, evidence of a *syn* conformation around the glycosidic bond. The 3D structure of d(GGGC-TTTT-GGGC) stabilized by 100 mM Na^+ is shown in Figure 12(a). The quadruplex has four grooves, of which two are equivalent and wide-formed within each hairpin.

Figure 12 Structure of quadruplex formed by d($G_1G_2G_3C_4T_5$-$T_6T_7T_8G_9G_{10}G_{11}C_1$) stabilized by 100-mM Na^+ (a), and by 100-mM K^+ (b). (Reproduced by permission of Bouaziz et al., *J. Mol. Biol.*, (1998).[63] Academic Press.)

The other two grooves are nonequivalent and narrow and are formed by the G1-G2-G3-C4 and G9-G10-G11-C12 interstrand interactions.

An interesting isomerization occurs in the molecule upon shifting from Na^+ to K^+ as the predominant counterion in the sample solution.[63] The change is manifested as distinctly different features in the proton NMR spectrum (Figure 11b). The spectrum of exchangeable protons shows that the molecule remains in a structure of two-fold symmetry, but that the basepairing pattern is different with K^+ ions present. The cytosine amino protons no longer appear close together, instead two of them have shifted upfield, indicating that they are no longer hydrogen bonded. The NOESY crosspeaks indicative of G·C·G·C tetrads (i.e. between H8(G1) and H5(C4) and between H8(G9) and H5(G12)) are not observed in the K^+ form of the quadruplex. A basepairing scheme for the G·C·G·C planes of the quadruplex with intrastrand Watson–Crick hydrogen bonds, but without pairing interactions in between the two strands was concluded. The K^+ stabilized structure remains a quadruplex (Figure 12b), but one with different hydrogen bond patterns in the outer tetrads and with T4-loop structures that differ from the ones seen in Na^+ solution (Figure 13).

A novel method of directly localizing the cation binding sites in DNA quadruplexes has been reported.[64] The $^{15}NH_4^+$ ion was used as a probe of cation coordination of G-tetrads, replacing Na^+ or K^+. In ^{15}N filtered proton spectra of the *Oxytricha nova* telomere sequence $d(G_4T_4G_4)$, the ammonium ions showed three distinct peaks at low pH. These could be assigned to NH_4^+ ions bound to two different DNA sites, populated as 2:1, while one much larger peak arises from bulk NH_4^+. From ROESY and NOESY experiments the ammonium ions could be mapped to loci between the planes of the G-tetrads (cf. section 2.2). Two more ammonium ions, one on either end of the quadruplex, are bound between the central G4 tetrads and its flanking outer tetrad. From measurements of the resonance line widths of the coordinated NH_4^+, their lifetimes were estimated to over 50 ms for the outer ions [N.V. Hud, P. Schultze, V. Sklenář, J. Feigon, 'Binding Sites and Dynamics of Ammonium Ions in a Telomere Repeat DNA Quadruplex', *J. Mol. Biol.*, **285**, 233–243 (1999)]. From chemical exchange N_2-Ex-HSQZ experiments with varying mixing times it was estimated that ammonium ions binding to the inner sites have residue times as long as 250 ms. These experiments also gave evidence for a pathway along which the NH_4^+ ions enter the quadruplex through the end openings of the cavity running along the helix axis and not through the grooves.

Figure 13 Details from structure of $d(G_1G_2G_3C_4T_5T_6T_7T_8G_9G_{10}G_{11}C_1)$ stabilized by 100-mM Na^+ (a) and (b) and 100-mM K^+ (c) and (d). 3.1.4 DNA–Drug Complexes

DNA interacting with small molecules will here be represented by the binding of the chiral transition metal complex $[Ru(phen)_3]^{2+}$ and the oligonucleotide $[d(CGCGATCGCG)_2]$.[65] The propeller shaped Ru-complex binds to the oligonucleotide with some sequence preference and with exchange kinetics that are rapid on the NMR timescale (milliseconds). While the fast kinetics precludes determination of a well-defined DNA–metal complex structure by NMR methods, conclusions about the type of interaction and its effects on the structure of the DNA oligomer can be reached.

Figure 14 shows the change in the aromatic region of the one-dimensional proton spectrum as the Ru/oligonucleotide duplex concentration ratio increases. Most notably a few resonances, both of the oligonucleotide and of the phenanthroline ligands, shift drastically as more Ru-complex is added. These chemical shift changes can be used to estimate binding constants for the metal complex, which were found to be in the range of 10^3–10^4, and also to provide evidence for sequence and groove specific interactions. In the sequence studied the most marked effects are seen around the central AT step where the chemical shift of the H2 proton of adenine reports drastic alterations in its local environment. Crosspeaks in NOESY spectra of the $[Ru(phen)_3]^{2+}$–oligonucleotide complex supplied strong evidence for binding in the AT region of the minor groove – many intermolecular NOEs of varying intensities were observed. The NOESY data also indicates that the DNA molecule does not undergo any significant structure changes but remains in a B-like conformation, and that the metal complex binds in a nonintercalative fashion.

Figure 14 (a) Δ-$[Ru(phen)_3]^{2+}$, (b) aromatic region of one-dimensional proton spectrum $[d(CGCGATCGCG)]_2$ and Δ-$[Ru(phen)_3]^{2+}$ in D_2O solution at 41 °C. Ru/DNA–duplex concentration ratios are indicated to the right, and the phenanthroline resonances and the H2 and H8 resonances of A5 are indicated on each spectrum.

3.1.5 DNA–Protein Complexes

The structure of the lymphoid enhancer-binding factor (LEF-1) to a 15 basepair long DNA oligomer will serve here to exemplify DNA–protein complex structures. The high-mobility group (HMG) of LEF-1 from mouse, containing 84 amino acids, was bound to the oligonucleotide 5′-CAC**CCTTTGAAG**CTC·CAG**CTTCAAAGG**GTG-3′ (bold face representing the protein binding site) in a 1 : 1 stoichiometric ratio, and the structure was determined by NMR methods.[66] Uniformly ^{13}C,^{15}N labeled LEF-1 and an extensive array of 2D and 3D experiments were used. The DNA portion of the complex was assigned from 2D ^{13}C,^{15}N double half-filtered NOESY and ^{13}C half-filtered NOESY and ^{13}C-decoupled homonuclear proton NOESY spectra. NOE crosspeaks between LEF-1 and DNA were identified from a 3D ^{13}C-edited ^{12}C-selected NOESY experiment. The structure determination was based on nearly 1450 intraprotein, 325 intra-DNA and 332 intermolecular distance constraints, and 42 dihedral angle constraints for the protein. The HMG domain of LEF-1 is dominated by three α-helices arranged to give it an L-like shape. The protein is wrapped around the DNA, forcing it to bend into a compressed major groove. Intimate protein–DNA contacts are formed between a concave surface of LEF-1 and the minor groove of the oligonucleotide where a methionine side chain is partly intercalated, wedging into the DNA without disrupting any of its basepairs.

3.2 RNA

3.2.1 Choice of Domains

Many RNA molecules of interest are prohibitively large for structure determination using NMR methods. This problem can often be circumvented by reducing the size of the RNA molecule of interest to a minimum portion that retains its specific functions. In some cases the anticipated secondary structure of an RNA molecule can suggest how such reductions may be performed without excluding vital interactions. A few structure motifs have been observed to reoccur in several RNA structures. The UUGC and GNRA tetraloops (where N signifies any base and R signifies a purine) are examples of this. The stable GNRA loop has also been used to cap a shortened stem or to connect loose ends, for example in the U1A binding RNA polyadenylation inhibition element.[67] The stability of the GNRA loop has been found to form a network of heterogeneous hydrogen bonds and extensive base stacking within the loop, explaining its unusual stability.[68] It should also be kept in mind that an RNA molecule that specifically binds to a ligand may not be correctly folded, or may not even adopt a stable structure, in the absence of its cognate molecule. An example of this is given by the AMP (adenosine monophosphate) aptamer RNA.[69] Furthermore, magnesium ions often play important roles in RNA structure stability.

3.2.2 Examples of RNA Structures

3.2.2.1 Adenosine Monophosphate–RNA Aptamer

An RNA aptamer structure can be nicely illustrated by an ATP (adenosine triphosphate) specific sequence of which

Figure 15 Sequence of AMP aptamer RNA.

the structure has been determined by NMR methods. In vitro selection performed on a column to which ATP was attached via a linker to its C8 position, combined with enrichment procedures, yielded a consensus sequence from a pool of RNAs 169 nucleotides long.[70] This sequence could be shortened to a 40-mer containing an 11 nucleotide consensus sequence (Figure 15) keeping its ATP affinity, which was characterized by a K_d (dissociation constant) of about 10 μM. The affinity was found to be the same for adenine and AMP as for ATP, and to increase upon raising the concentration of Mg^{2+}. The aptamer molecule was, based on its sequence, proposed to adopt a structure containing an internal loop opposite an invariant guanine, flanked by two basepaired stems. This prediction was confirmed by two independent structure studies. The 40-mer RNA aptamer, shown in Figure 15, in a complex with AMP was determined by Jiang et al.,[71,72] and Dieckmann et al.[73] have determined a closely related 36-mer RNA–AMP.

Structure determination by NMR methods revealed that the conserved internal loop and the bulged guanine fold around the ATP in a compact manner, embracing most of the purine portion of the AMP, leaving only its C8 edge exposed (Figure 16). The backbone of this portion of the RNA has been likened to a Greek zeta (ζ). The loop nucleotides G8, A9 and A10 combine with the AMP to stack in a way similar to a GNRA turn.[68] Two asymmetric G·G mismatch basepairs, one of them involving the bulged G34, cap the two helical stems that extend from the loop, giving the entire aptamer an L-like shape. Based on nearly 40 intermolecular NOEs between the AMP and several of the bases in the loop, the AMP could be located quite precisely. The AMP was found to stack between the A10 and G11 bases of the RNA loop. The RNA molecule was found to undergo an AMP-induced structural transition,[69] evidenced by the appearance of 10 new resonances from exchangeable protons upon addition of AMP.

Assignment of the ATP aptamer complex presented challenges, not only because of the size of the system, but also because of the unknown structure of the internal loop which, in combination with the large number of NOEs observed, makes it difficult to distinguish sequential from long-range interactions. For the unambiguous assignment

Figure 16 Solution structure of the AMP–RNA aptamer complex, sequence shown in Figure 15. RNA is represented by ribbons, the G1–G6·C35–C40 stem is colored blue, the G19–C32 hairpin portion is colored green, and the large G7–G17 loop is colored in red–yellow shades. The bound AMP molecule is shown in stick representation in white. Insert shows AMP in blue and RNA in surface representation. (Reproduced by permission of Dr. D.J. Patel of Sloan-Kettering Institute, New York.)

of the AMP aptamer, a variety of multidimensional experiments were carried out on samples of unlabeled and uniformly ^{13}C and ^{15}N labeled RNA and AMP. The use of labeled RNA in a complex with unlabeled AMP, or vice versa, permitted the distinction of intra- from intermolecular NOE interactions involving the RNA and AMP molecules.[72,74]

Identification of exchangeable proton resonances in the internal loop can be approached by different strategies.[74,75] Site-specific ^{15}N labeling of RNA purines (N1 imino and N2 amino positions in guanines and N6 amino positions in adenines) of most purines one at a time in the loop and bulge regions of the AMP–RNA aptamer made possible the assignment of the exchangeable protons in this region. The specifically isotope-labeled bases required for this strategy may, however, not be readily available. In an alternative approach, the guanines of the internal loop and the bulge guanine were systematically substituted for inosine. The replacement by inosines causes a downfield shift of nearly 2 ppm of the corresponding imino proton, facilitating its assignment. However, some of the inosine-for-guanine substitutions resulted in weakened binding of AMP, suggesting cautious use of

the inosine substitution strategy.[75] One assignment of special importance for this structure is the proton of the 2′-hydroxy group of G34, which shows a large number of NOEs to surrounding RNA and AMP protons. This hydroxy proton was identified from its appearance as a singlet peak in spectra of uniformly ^{13}C and ^{15}N labeled RNA recorded without decoupling, thus excluding it from being attached to a carbon or a nitrogen atom. It is notable that the OH-proton appeared extensively downfield shifted (9.34 ppm) compared with previously observed hydroxy proton resonances (ca. 6.8 ppm in the UUGC loop[76]).

The exchange rates of RNA imino protons have been measured in the AMP–RNA aptamer complex.[77] The study reported that the imino protons around the ATP-binding loop containing several non-Watson–Crick basepairing interactions are stabilized by ATP complexation, as well as those in its surrounding stem basepairs. Furthermore, the exchange time of the sugar 2′OH proton of G34 (Figure 15) was measured successfully and found to be about 20s, which is very long compared to the corresponding 2′OH in a ribonucleoside monomer (<1 ms), lending strong support to this hydroxy group participating in hydrogen-bond formation.

3.2.2.2 RNA–U1A Protein As a representative structure of RNA–protein complexes determined by NMR, the human U1A protein bound to an RNA molecule containing the polyadenylation regulatory element of the pre-mRNA 3′-UTR (untranslated region) will be discussed. The 30 nucleotide long RNA sequence, shown in Figure 17, contains a flexible internal loop, which becomes ordered when binding to the protein. The RNA binding domain of U1A comprises residues 2–102, and contain the amino terminal ribonucleoprotein domain. For reasons of sample stability the U1A protein studied contained two mutations of amino acids not directly involved in RNA recognition, which gave a K_d of less than 10^{-9} M with the RNA construct. The strategy chosen for assigning the RNA–protein complex was to make extensive use of previously obtained assignments of the free components.[78] This was found attractive partly because of the higher spectral quality of the individual components compared with the complex. The RNA component had been previously assigned both alone and in complex with U1A.[67] Resonances originating from the protein and the RNA resonances and their respective NOE crosspeak patterns were distinguished in spectra of the complex, based on their chemical shift differences – RNA only rarely gives rise to signals upfield of 3.5 ppm – and from spectra of complexes containing double-labeled protein. The helical portions of the protein were mostly unaffected by RNA binding, except for one of the helices for which large chemical shift changes occur. Only a minority of the amino acid residues could not be assigned from comparison with free protein. For these residues heteronuclear through-bond correlation data obtained with $^{13}C/^{15}N$ double-labeled protein was used.

Intermolecular interactions were observed selectively through 2D half-filtered experiments on isotope-labeled protein in complex with unlabeled RNA.[79] Most intermolecular NOEs were identified from 3D ^{13}C-edited spectra of labeled protein in complex with unlabeled RNA. In total more than 2600 unambiguous distance constraints were used for structure refinement. A majority of these, over 1700 constraints, came from intramolecular protein interactions, near 600 from the RNA internally and 123 constraints were intermolecular. In addition, more than one hundred dihedral angles and 25 hydrogen bonds were used to determine the RNA component.[78] The resulting structure, Figure 18, shows that the RNA molecule is severely kinked and that its helical parts interact with the variable loops of the protein. The β_2–β_3 loop

Figure 17 Sequence of U1A binding RNA.

Figure 18 Structure of the RNA binding domain of human U1A bound to the RNA binding portion of the polyadenylation regulatory element of the U1A pre-mRNA 3′ UTR studied by Allain et al.[5] Protein shown in space filling (cyan), and RNA shown in stick representation. RNA residues interacting with the protein are shown in orange and magenta.

protrudes through a hole in the RNA formed between the internal loop and the helical stems. The single stranded residues of the RNA internal loop are splayed out across the surface of the β-sheet of U1A, with each of the nucleotides engaged in intra- or intermolecular stacking or hydrophobic interactions with other bases or aromatic protein side chains.

3.3 PNA and Other Variations

A growing interest in employing the basepairing specificity of nucleic acids to target specific genes has spurred the development of nucleic acid analogs tailored to combine improved function with desired properties (reviewed by Mesmaeker et al.).[80] Several modifications of the DNA backbone have been implemented in this pursuit, including substitutions within the phosphate groups and modification of the sugar moieties, as well as replacement of the entire sugar phosphate skeleton by a peptide-like chain, as in PNA (Figure 1). Insights into the structure of these DNA analogs may lead to an understanding of their function, as well as suggesting ways of modifying them for improved applicability. PNA forms stable hybrid duplexes with both DNA and RNA, and forms PNA·DNA–PNA triplexes with purine-rich DNA strands.[81]

3.3.1 PNA–DNA Hybrid Duplex

The structure of the PNA–DNA hybrid H-GCTATGTC-NH_2·d(GACATAGC) has been studied.[6] Generally assignment strategies of PNA protons need to be tailored to the specific system. In the instance of a PNA–DNA duplex the assignment of the PNA strand was complicated because of the lack of an easily observed continuous sequential crosspeak pattern along the exchangeable portion of the PNA protons. Instead, aromatic–methyl crosspeaks within thymines and their flanking residues were used to identify sets of three residues, which, along with similar patterns around H5–H6 interactions in cytosines, allowed assignment of all aromatic protons. The imino resonances, assigned via the DNA strand were, together with the adenine H2 crosspeaks, useful for confirming these assignments and for assigning additional exchangeable basepairing protons. The amide resonances were assigned from their NOEs to the H6/H8 protons on their own and N-terminal side flanking residues. The amide–aromatic NOEs observed in H_2O solution provide a pattern that may be amenable to sequential assignment. Scalar interactions, seen as TOCSY crosspeaks, were seen between backbone amide protons and the intraresidue H4′ and H5′ protons of the preceding residue. Each aromatic H6/H8 proton on the PNA strand shows several NOEs to the C7′, C4′ and C5′ methylene protons, which confirm the assignments of these protons. The pattern in the aromatic–sugar region of a NOESY spectrum shows typical B-form characteristics such as *anti* glycosidic bonds and near C2′-*endo* sugar conformations for the DNA strand.[82] Determination of the 3D structure of the hybrid duplex revealed a B-like conformation with a wide major groove and a narrower minor groove.[6] Somewhat irregular basepair stacking was observed and was supported by an unusually dispersed imino proton spectral region and by several interstrand NOE interactions. The structure of this PNA–DNA duplex is in many ways similar to the Watson–Crick portion of a PNA·DNA–PNA triplex structure that was determined by X-ray crystallography methods.[83]

3.3.2 PNA–RNA Hybrid Duplex

A PNA strand basepaired to an RNA oligonucleotide adopts a different conformation and requires different assignment strategies. Assignment of a PNA–RNA duplex was accomplished by incorporating a single fully $^{13}C-^{15}N$ labeled thymine residue in the PNA strand,[84] which was helpful in several ways. First, it helped to identify the labeled residue in double quantum or TOCSY spectra. Second, through NOESY experiments its neighboring residues could be identified. Third, 2D ^{13}C filtered NOESY experiments were useful for characterizing the local backbone conformation. Sequential NOE connectivities were observed throughout the PNA strand. The structure of a PNA–RNA hexamer duplex was determined and found to be in an A-like conformation with C3′ *endo* sugars in the RNA strand. The PNA strand backbone has many features in common with the one of the PNA–DNA hybrid.[81]

4 FUTURE OUTLOOK

New developments are under way that will move the horizon of the impossible further away. Most of the newly developed techniques work more efficiently at higher magnetic fields, and hence may be increasingly used as NMR instrumentation becomes further advanced.

4.1 Transverse Relaxation

Transverse relaxation optimized spectroscopy (TROSY) is a new technique used to measure scalar couplings in large molecules. TROSY experiments have been used to measure $^{15}N-^{15}N$ and $^{15}N-^{1}H$ couplings through hydrogen bonds in DNA and should be applicable to large molecules such as nucleic acids in complexes with proteins.[85]

4.2 Oriented Samples

Newly developed NMR methods that use the addition of matrixes to the sample in order to accomplish a net orientation of the sample, have proven powerful for protein structure determination.[36] By measuring the orientation of vectors in the molecule (derived from different coupling constants measured at different magnetic field strengths), the orientation of molecular vectors such as amide and carbonyl bonds can be determined independently relative to the magnetic susceptibility tensor of the molecule. The magnetic susceptibility is relatively large in aromatic molecules, particularly when ordered in a stacked manner. Thus nucleic acid molecules give efficient contributions to the measurability of dipolar couplings. The dipolar effects increase as the square of the magnetic field strength and can therefore be expected to become a more studied phenomenon as higher field NMR instruments become available. Dipolar couplings were measured and used to determine the structure of the DNA binding domain of the transcription factor GATA-1 bound to an oligonucleotide.[86] In a different study the addition of a filamentous bacteriophage was used to increase the degree of anisotropy in the sample and it was shown that in addition to heteronuclear dipolar couplings, $^{1}H-^{1}H$ dipolar couplings could also be measured.[37] These recent developments may present a novel approach to one of the holy grails of DNA structures – the overall shape and the extent of any sequence-dependent bend of a molecule – which traditional methods that rely on short-distance constraints that easily accumulate small errors have failed to answer.

ACKNOWLEDGMENTS

I am grateful to Dr. Asif Suri and Mr. Tommi Ratilainen for their assistance in figure preparation, and to Dr. Bengt Nordén for valuable comments on the manuscript.

ABBREVIATIONS AND ACRONYMS

AMP	Adenosine Monophosphate
ATP	Adenosine Triphosphate

The general relations between structure and energetics of nucleic acids are described. A detailed, multileveled definition of the structures adopted by one, two, three and four strands is presented, with emphasis on the chemical functionalities of the structural subcomponents. Descriptions include results from studies of the thermodynamics of transformations and structures (e.g. double helix formation, superhelical coiling). Different aspects of this large array of problems have been determined using X-ray diffraction and spectroscopic techniques, such as ultraviolet (UV) and infrared (IR) absorption, circular dichroism (CD), Raman scattering and nuclear magnetic resonance (NMR). Interactions, within one strand or between two or more strands, with cations, buffers, aromatic chemicals and proteins are all described. Methods include spectroscopy, calorimetry and computational approaches (statistical mechanics, molecular mechanics, dynamics, quantum mechanics). A Further Reading section is included to provide an idea of the vast scope of this area.

1 INTRODUCTION

The foundation of life itself is encoded by a vast array of nucleic acids. The functional capability of a particular nucleic acid in its biological niche is determined by the viability of its physical structure. As with all chemical species, the assumed structure is a compromise between stabilizing and repulsive interactions between and among the functional subcomponents. The relations between structure, function and energetics are complicated, and therefore require a detailed, multileveled definition. The structures of nucleic acids are so varied and numerous that we can only summarize a broad selection of the key areas. A much less inclusive selection of the associated energetics is discussed, only providing an overview of general approaches. The cited literature expands upon the methodology, assumptions and interpretations, presenting a reasonably broad, but by no means exhaustive, perspective of the subject.

2 ORGANIZATION OF STRUCTURAL HIERARCHY

Nucleic acid structure are classified in a hierarchical manner, beginning with the simplest components and proceeding to progressively larger assemblies. Associations between two or more simple subcomponents produce secondary and tertiary structures. We use the term ''superstructure'' to define the even larger functional domains occupied by nucleic acid components in more complex assemblies (e.g. supercoiled chromatin, virus capsids).

2.1 Components and Linkages

The basic structural components of nucleic acids include the sugars ribose in ribonucleic acid (RNA) and deoxyribose in deoxyribonucleic acid (DNA). Both polymers are composed of two or more nucleotides connected by phosphates, which are connected by sugars ribose and deoxyribose, respectively. Each sugar has one attached nucleobase (Figure 1a–d) which connects noncovalently with other strands through base pairing mediated by interbase hydrogen bonds (Figures 2a and b, 3 and 4a–c).[1] The 2′ carbon of deoxyribose does not contain

Figure 1 Geometries of a nucleosides in the *syn* and *anti* orientation. (a) Adenosine and uridine are in the *anti* conformation. (b) 8-Bromoguanosine (br^8G) and 6-methyluridine are *syn* owing to their bulky substituents *ortho* to the glycosidic bond. In br^8G, an intramolecular −O5′H•N3− hydrogen bond stabilizes the *syn* conformation. The C3′-*endo* sugar puckering is preferred by the *anti* conformation; C2′-*endo* is preferred by *syn* nucleotides. Spheres of increasing size represent H, C, N, O atoms; atomic positions obtained from crystal structure analysis. (c) Nucleotides in the C3′-*endo* and C2′-*endo* sugar conformations preferred in A- and B-form DNAs, respectively. The distances between adjacent P atoms in the sugar–phosphate backbone are indicated. (d) Energy map of furanose conformations as a function of pseudorotation phase angle (P). The latter is counted in a clockwise sense with $P = 0°$ in a vertical position. The puckering amplitude (q) corresponds to ν_{max} and increases radially from the central dot representing a planar furanose. The ring indicates the path of true pseudorotation with $q = 0.4$ Å; filled circles describe energies calculated when all five torsion angles ν_n are constrained to the path of pseudorotation; empty circles correspond to only ν_3 constrained and other torsion angles relaxed. Note large differences at $P \approx 270°$ (O4′-*exo* puckering). Drawn molecules show relaxed geometries and belong to nearest neighbor circles in the energy plot. The nomenclature and orientation are given on the molecule $P = 0$ (top of circle). Numbers on the diagram indicate energies (kcal mol^{-1}) above global minimum. Saenger, *Principles of Nucleic Acid Structure*, Springer, Berlin, 21, 63, 1984, Copyright Springer-Verlag 1984, and of John Wiley and Sons from D. Voet, J.G. Voet, *Biochemistry*, John Wiley & Sons, New York, 808, 1990.)

a hydroxyl group. This distinction separates the natural nucleic acids into the two major classes, RNA and DNA. The 2′-OH group in RNAs participates in alkali-catalyzed hydrolytic chain breakage, when the hydroxide attacks and binds the adjacent 3′ phosphodiester phosphorus and eliminates the 3′-terminal chain. In contrast, DNA, which has a hydrogen at the 2′ carbon, is relatively resistant to chain breakage. As a result, the transient functions of RNA rely on its natural tendency toward breakdown.

RNA functions to provide a source of encoded ''molecular information'' made from the genomic DNA via transcription. Messenger RNA (mRNA) is used to make protein during translation (''gene expression''). The tendency of RNAs to break down allows cells to reabsorb their used mRNAs, leading to genetic ''information turnover''. Many, many other functions of RNA have been described.[2,3] In contrast, DNA functions as a reservoir of relatively stable stored information (like computer permanent memory, ROM) which is decoded during transcription to produce RNA. DNA also participates in replication, to make a daughter genome from the copy provided by the maternal genome, recombination (to swap and reassociate DNA fragments) and many other aspects of genetic metabolism.

The term ''glycosidic bond'' refers to the covalent linkage between the C1′ carbon of the sugar and N1 nitrogen of pyrimidines or N9 of purines, the heterocyclic nucleobases (Figure 2a and b). Sugar ''pucker'' variants of the pentose rings include C2′-*endo* and -*exo*, and C3′-*endo* and -*exo* (Figure 1b and c). These conformations can interconvert by the pseudorotation process, in which one atom is viewed as being out of the plane formed by the other four atoms (similar to the appearance of the corner of an envelope) then another atom becomes the nonplanar one, and so on to create a cycle of stepwise conformational exchanges about the periphery of the sugar ring.

The C2′-*endo* pucker projects the atom out of the plane of the other ring carbons toward the nucleobase. This pucker variant is favored in the structure of B-DNA (Figure 4a) by a few kilojoules per mole over the other predominant pseudorotation variant, the C3′-*endo* sugar pucker. The C3′-*endo* sugar pucker projects the C3′ carbon out of the plane toward the nucleobase (Figure 1c and d). This conformation occurs in the A-form (Figure 4b) structures adopted by both DNA and RNA. Both types of pucker variants are found within the zig-zagged backbone of Z-DNA (Figure 4c).

The sugar residues of nucleic acids are often modified. For example, in 2′-*O*-methylated ribose, a methyl group forms an ether linkage, sharing the hydroxylate oxygen with C2′. Sugar modifications are found in transfer RNAs (tRNAs)[1] and in the C/D box of small nucleolar RNA (snoRNA).[2] The snoRNAs are used to specify sites for enzymatic methylation of nucleolar rRNAs to the methylase(s).

Figure 2 (a) Atomic numbering scheme and definition of torsion angles for a polyribonucleotide chain. Counting of nucleotide from (a) to (b), i.e. in the direction O5′ → O3′. Hydrogens at C5′ and oxygens at P are differentiated by 1 and 2 according to the rule given in the text. In deoxyribose, the hydrogen replacing O2′ is labeled 1 and the other is 2. (b) Fragment of RNA with sequence adenosine (A), guanosine (G), uridine (U) and cytidine (C) linked by 3′,5′-phosphodiester bonds. Chain direction is from 5′- to 3′-end as shown by arrow. Atom numbering scheme is indicated in one framed nucleotide unit, 5′-GMP. All hydrogen atoms drawn in A and only functional hydrogens in other nucleotides. In short notation, this fragment would be pApGpUpCp or pAGUCp. In DNA, the hydroxyl attached to C2′ is replaced by hydrogen and uracil (U) by thymidine. The second major structural component of nucleic acid structure is the phosphodiester backbone, which joins the nucleotides together (Figures 2–4). The 5′-hydroxylate of one nucleotide is covalently bound to the 3′-hydroxylate of the next ''upstream nucleotide'' in the sequence. By convention, sequences are always listed from the end with the free 5′-hydroxyl group (the 5′ terminus) to the 3′ terminus, the other end of the $(\text{phosphodiester})_i$ strand (where *i* indicates the number of nucleotide residues).

At physiological pH, the exposed hydroxyl groups of the phosphate backbone are deprotonated, producing a negatively charged backbone, with one anionic site per nucleotide. This polyanionic nature of nucleic acid structures plays a predominant role in the physical, chemical and functional properties of these biomacromolecules. Mono- and polyatomic cations bind to this feature of the external surfaces of nucleic acid structures, modulating their stabilities and sometimes inducing significant structural transformations.

Synthetic modifications of the phosphate backbone have been produced for biotechnological applications. For example, in phosphorothioates a sulfur atom is covalently linked by a double bond to the central phosphorus atom, replacing the carbonyl oxygen. As a result, the backbone is nuclease resistant and the nucleic acid has an extended functional lifetime. Methyl groups may also be covalently linked to the phosphate groups in place of the carbonyl oxygen. These methyl phosphate modifications also impart nuclease resistance.

The nucleobase sequence confers structural specificity and uniqueness to a given nucleic acid. There are two general classes of nucleobases, purines and pyrimidines. The bicyclic purines, adenine (A) and guanine (G), are found in both DNA and RNA. In canonical Watson–Crick (WC) base pairs, these purines form hydrogen bonds with the monocyclic pyrimidines – thymine (T) in DNA and uracil (U) in RNA – and cytosine (C) (Figure 3).

T and U differ only in the replacement of an exocyclic methyl group found in T by hydrogen.

Modified nucleobases occur in many nucleic acid species. The RNA nucleobase U is methylated to form the DNA base (T, really m^5U). The content of the developmentally important modified base 5-methylcytosine (m^5C) differs in the chromosomal DNAs of wild-type and diseased cells.[4] A more complicated modification, found in some bacterial virus DNAs, involves covalent attachment of a glucose ring to a C5-hydroxyl group on C. Another example involves enzymatic methylation of A N1, which is required to protect the duplex DNA from restriction enzyme cleavage.

Modified nucleobases are very common in natural RNAs, especially transfer RNA (tRNA).[1] For example, nucleobases are methylated at all ring positions. Two common RNA base variants, pseudouridine and dihydrouridine, occur in all tRNAs. Pseudouridine is a U that is attached to ribose at C5 instead of N1. Dihydrouridine is structurally similar to uridine, except the aromatic ring is saturated at the 5,6 π-bond, making dihydrouridine much more flexible than uridine. Dihydrouridine is always present in tRNA (at position 17) and common in small nuclear and nucleolar RNAs. More complex modifications, composed of isopropyl groups, amino acid side chains, and many others, have been described. A particularly useful example, the three-ringed G derivative wyebutine, allowed early researchers to isolate phenylalanyl transfer RNA ($tRNA^{Phe}$), by virtue of its hydrophobicity, and detect it, since the base is highly fluorescent. These complex functional groups can affect the kinetics of biological reactions by modifying the chemical and physical properties of the nucleic acids and, as a result, their propensity to move freely, bury themselves, become deprotonated, react with or shun other charged entities, etc.

2.2 Secondary Structure

The sequence of nucleobases is referred to as primary structure. Interactions between nucleotides within the same strand or another strand produce secondary structures. Natural DNA molecules most commonly consist of double-helical (duplex) strand variants (Figures 2–4). In contrast, RNAs usually form complex globular structures more like those found in proteins. RNA structures are typically comprised of stem–loop (hairpin) pairings, a common subdomain, formed when a strand pairs with itself and ''loops out'' a region (Figure 5a–d).

The primary energetic contributions to RNA folding result from the ''hydrophobic effect'', as found for globular proteins structures. However, ''despite the obvious analogies between the folding of proteins and RNA, key differences remain. An important factor in the folding of RNA is that condensation of a polyanion is necessarily sensitive to differences in ionic strength, as the electrostatic repulsion along the backbone provides a strong opposing force to the collapse of hydrophobic bases. Nearly all complex RNAs require Mg^{2+} for biological activity, both to stabilize the native structure and help mediate catalysis. Magnesium binding is cooperative and coincides with the formation of tertiary structure''.[5]

Figure 5 Secondary structure motifs. (a) Hairpin. A hairpin is formed when an RNA strand folds back on itself. The stem of the hairpin can consist of any number of WC base pairs. In principle, the loop may contain any number of unpaired nucleotides. The smallest loop thus far observed in RNA has three nucleotides. (b) Bulges. Unlike an internal loop, a bulge has unpaired nucleotides on only one strand. The other strand has uninterrupted base pairing. The base pairs on either side of a bulge may stack to form a regular helix. In a single-base bulge, only one unpaired nucleotide interrupts the paired region. (c) Internal loops. In an internal loop, at least one base is unpaired in each strand of the loop separating two unpaired regions. A mismatch is a special type of internal loop; only one nucleotide is unpaired on each strand. Any two bases may be in apposition. (d) Junctions. A junction occurs when double-stranded regions, separated by any number of unpaired nucleotides, come together. Three-stem junctions are the smallest; when two stems separated by unpaired nucleotides adjoin, either a bulge or internal loop is formed. Four-stem junctions are characteristic of tRNAs. Five stems are the most that adjoin in 16S ribosomal RNA. (Reproduced from J.R. Wyatt, J.D. Puglisi, I. Tinoco, Jr, *Bioessays*, **11**(4), 104 (1989). Copyright © 1989 John Wiley & Sons. Reprinted by permission of Wiley-Liss, Inc., a division of John Wiley & Sons, Inc.)

Kinetic studies have suggested that RNA folding can occur sequentially, following a defined pattern. The ''folding funnel'' concept captures the idea that polymers fold by descending down an energy gradient.[5] Folding is depicted symbolically as one or more ''funnel spouts'' with different ''energy topologies''. The shape indicates the relative intrinsic propensities of chains to fold correctly, become trapped in an intermediate conformation(s), remain unfolded, etc.

Small proteins and other RNAs can enhance the rate of RNA folding processes and increase the net stability of

the folded domain. One very important class of stabilizing agents is the counterions, including mono- and divalent cations and organic nitrogen-based polycations, which offset the high anionic charges that would otherwise result in strand–strand repulsion.

2.3 Superstructural Considerations

The most common higher order structure assumed by DNA is the supercoil (Figure 6a and b). Supercoils are induced by and stabilized by negative superhelical torsional stress. This energy source helps, along with the histone proteins, to produce the high degree of compaction necessary to package the genomic DNA within the relatively small volume of the nucleus. Supercoiled structures are found in circular duplexes (i.e. plasmids) or in molecules that are rotationally constrained at both ends, as in the case of chromosomes in vivo, which are segregated into separate scaffold-bound subdomains. Another important class of contributors to the compacted

Figure 6 (a) Description of the interrelation between linking (L_k), twisting (T_w) and writhing (W_r). Unstrained, relaxed B-DNA with 420 base pairs has 42 turns of one strand wound about the other, $L_k = T_w = 42$ and $W_r = 0$ (top). If, now, the DNA is held tight at the left end, and the right end is rotated clockwise by six turns so the double helix is partially unwound, L_k and consequently T_w reduce to 36. This DNA can again be circularly closed with $L_k = T_w = 36$ and $W_r = 0$, i.e. compared with the above picture, base pairs of six turns are disrupted. Owing to the tendency of DNA to retain the B-DNA form, however, T_w increases to the original $T_w = 42$ with 420 base pairs. However, since L_k is a topological number, it is constant, $L_k = 36$ and [in order to satisfy Equation 19-1 in the original publication] the writhe must become $W_r = -6$, corresponding to a right-handed supercoil (superhelix) with six cross-overs. (b) Sedimentation rate of closed circular duplex DNA as a function of ethidium bromide concentration. Intercalation of ethidium between the base pairs unwinds the double helix. Since the linking number of the circle is constant, this is accompanied by an equivalent increase in the writhing number. As the superhelix unwinds, it becomes less compact and sediments more slowly. At the low point on the curve, the circular DNAs (plasmids) have bound sufficient ethidium to become fully relaxed. As the ethidium concentration is further increased, the DNA supercoils in the opposite direction. The supertwisted appearances in the depicted DNAs have been characterized by electron microscopy. (Reproduced by permission of Springer-Verlag from W. Saenger, *Principles of Nucleic Acid Structure*, Springer, Berlin, 452, 1984. Copyright Springer-Verlag, 1984, and of John Wiley and Sons from D. Voet, J.G. Voet, *Biochemistry*, John Wiley & Sons, New York, 820, 1990.)

Figure 6 (*Continued*)

DNA structure found in the nucleus are the highly electropositive DNA-binding proteins, especially the histones around which the DNA wraps in approximately 200 base pair segments to form the ''beads on a string'' motif.[1–3] Thus, charge neutralization plays a crucial role in accommodating DNA in its natural niche.

3 DNA STRUCTURE

The delineation of the details of DNA and RNA structures has benefited tremendously from X-ray crystallographic techniques, in which highly ordered crystals are formed and illuminated with narrowly collimated X-ray light. The diffraction angles and intensities of spots produced by the light beam are used to calculate distances and angular relations between atoms in the molecular lattice. The crystals have been difficult to produce, so only limited information is available, especially for RNAs. Structures of a moderately large set of duplex DNAs have been determined best exemplified by the very well-resolved dodecamer fragment studied by Dickerson et al.[6] Structures of left-handed DNAs, four-stranded quadruplex DNAs, mismatched and bulged DNA duplexes, a few tRNAs,[1] Group I intron RNA fragments, hammerhead RNAs[7] and some non-WC (mismatched) base-pair-containing RNA duplexes are described below and in the Further Reading section.[8]

3.1 Duplex Structures

RNA and DNA molecules have very different intrinsic structural predispositions. The duplex structure occurs in most native DNAs and RNAs. DNAs are typically duplexes in long strands, whereas RNAs are usually formative subcomponents within more complex tertiary motifs.

The exact conformations adopted by strands in duplex DNA depend critically on sequence, salt and DNA concentrations, temperature and solution conditions (e.g. pH, presence and concentration of apolar or amphipathic solutes, ligands). The most common duplex conformation is the right-handed B-form (Figure 4a). The base pairs are centered on and rotate about the helical axis in a counterclockwise direction; the planes formed by the bases are perpendicular to this helical axis. B-form DNA is found in well-hydrated fiber preparations, as first discovered using X-ray diffraction results obtained by Franklin and interpreted by Watson and Crick.[1] This form predominates under physiological conditions. However, it is now known to occur in equilibrium with sub-helical domains consisting of the right-handed A-forms of DNA and conformations intermediate between

B- and A-forms (Figure 4a–c). Bases in the right-handed A-form helix are skewed slightly away from the helix axis and their planes are tilted about 18° away from it. A-form DNA is preferred in fibers that are less hydrated than those favoring the B-form.

At still lower relative humidity, alternating CG-block sequence DNAs readily adopt the left-handed Z conformation (Figure 4c).[9] This conformation is induced by torsional stress, rotating the nucleotides clockwise about the helical axis. Maintaining the antiparallel strand polarity twists the phosphodiester backbone, producing the characteristic zigzag pattern.

3.2 Triple Helical Structures

DNAs (and RNAs) also form triple-stranded (triplex) structures. Triplexes can be produced in supercoiled bacterial plasmid DNA of the correct sequence and in promoter sequences of eukaryotic genes.[10]

The triple helix is typically comprised of (pyrimidine)$_2$purine base triples in which the N7 face of the WC pyrimidine•purine base pair is associated with another pyrimidine residue (hydrogen bonds are symbolized using a centered bold dot, X•Y). The mode of pairing with the second pyrimidine residue is referred to as a "Hoogsteen interaction" (Figure 7a and b).[1,11] A number of compatible sequence variants have been described and the predisposition for triplex formation is very dependent on the length.

An interesting well-defined triplex structure is called H-DNA (Figures 8a and b and 9a).[11] This structure is characterized by mirror repeated oligopurine or oligopyrimidine sequences that loop a fragment of one strand out and coalesce together. One strand forms a stem–loop and the third of four segments binds to it; the fourth segment is the free loop. H-DNA only forms in extended regions of correct sequences and has been characterized by its susceptibility to S1 nuclease digestion. Although H-DNA maintains a triplex structure, it is comprised of two strands. When the mirror repeat segments coalesce, the axis of the

Acad. Sci. USA*, **85**, 3785 (1988).)

Figure 9 Triple-stranded H-form and cruciform DNAs. (a) Triple-strand H-DNA is stabilized by hydrogen bonding between the nucleobases to form base triplets. They are typically formed by sequences that are rich in purines in one strand and pyrimidines in the complementary strand. (b) Cruciform DNA is formed by inverted repeat sequences, with a dyad axis of symmetry between the two strands of the duplex. (Adapted from Prentice-Hall from K. Van Holde, W.C. Johnson, P.S. Ho, *Physical Biochemistry*, Prentice-Hall, Upper Saddle River, NJ, 59, 1998. Copyright © 1998 Prentice-Hall, Inc.)

DNA molecule bends. Consequently, structure formation requires input energy, which is supplied by superhelical stress.

Certain C-containing triplexes are stable at acidic pH and dissociate rapidly as the pH is increased above the pK_a for loss of the N3 proton.[11] Stabilization requires protonation of C N3, a prerequisite for hydrogen bond formation with unprotonated C to produce a hemiprotonated C•C_H^+ base pair. Methylating C can increase the tolerance to elevated pH, stabilizing the triplex by shifting the pK_a for protonation upward by ca. 0.2 unit.[12,13]

3.3 Four-stranded Structures

G-rich sequences common in telomeric and GC-rich promoter DNAs are highly predisposed to forming four-stranded quadruplexes. Unconfirmed proposals hypothesize that quadruplexes form and contribute to the mechanism of several processes, including the regulation of telomeric interactions, meiotic recombination, DNA methylation, gene expression and viral packaging. Quadruplexes form one-, two- and four-stranded inter- and intramolecular species, paired in both parallel and antiparallel conformations (Figure 10b and c).[14,15] The base-pairing motif, a G-quartet, is comprised of four coplanar bases that are hydrogen bonded to form a closed square (Figure 10a). They are right-handed twisted helical structures with *anti* G glycosidic conformations in most nucleotides, interspersed in some complexes with *syn* G residues.[16]

Quadruplexes are stabilized by monovalent cations C•C_H^+ base pair formation and m^5C inclusion.[13]

Figure 10 (a) "G-quartet" hydrogen bonding scheme. Phosphodiester backbone sugars are indicated by dR. (b) Quadruplexes formed from (i) one, (ii) two and (iii) four strands. Closed circles refer to guanines, small open circles indicate thymines and large open circles represent octahedral coordination complexes involving monovalent cations "caged" within two stacked G-quartets. (c) K^+-induced formation of G-quadruplex structure from the corresponding self-complementary WC duplex d(G_4C_4). (Reproduced from H. Deng, W.H. Branulin, *Biopolymers*, **35**, 680 (1995). Gaffney, *Science*, **250**, 544 (1990). Copyright 1990 American Association for the Advancement of Science.)

Among monovalent cations, potassium most stabilizes quadruplex formation, associating with the C6 carbonyl oxygens of guanosine residues to form cryptand complexes.[17,18] Physiological Mg^{2+} concentrations decrease the rate of formation of triplexes and increase the dissociation rate.[19] Competition between duplex, triplex and quadruplex depends sensitively on the nucleic acid concentration and type(s) and concentration(s) of mono- and divalent cations.[20] These folding and multimerization processes have been studied from many perspectives, demonstrating some intriguing properties.[21]

The four-stranded i-motif (i-tetrad) structure forms by interdigitation of two $C{\bullet}C_H^+$ paired parallel stranded duplexes (Figure 11a).[22] G-rich strands can form quadruplexes containing $C{\bullet}C_H^+$ and G-quartets.[10] The i-motif is an antiparallel tetrad with dyad symmetry that forms at acidic pH.[23] Cytidine protonation can occur near, at or even above neutral pH.[24] X-ray diffraction analyses showed that monoprotonated $C{\bullet}C_H^+$ base pairs form across the center of the helix, pairing the two diagonal pairs of strands, trapping the two duplexes by virtue of their interleaved base pairs, like two diagonally interlocked ladders. Interdigitation of the co-stacked duplexes brings the pairs in van der Waals contact.[23] Intercalation liberates a lot of free energy, producing a very stable structure.[25] Both types of four-stranded structures have two narrow minor grooves and two wider major grooves. The phosphate backbones are aligned in very close proximity, especially across the two minor grooves.[23]

The i-tetrad can form from a single telomeric strand. Interestingly, there are negligible differences in electrostatic interactions between the i-tetrad motif and the two identical duplexes from which it is comprised.[25] RNA cannot form the i-motif because the C2′ hydroxyl sterically hinders the intercalated geometry.

Similar to the competition between triplex and quadruplex conformation, duplexes may also change structure

Figure 11 (a) Proposed model of the d(TC_5) tetrad. Intercalation scheme of the two parallel duplexes. The terminal thymidine residues may not be base paired. There are three axes of twofold symmetry (arrows), one along the helix axis through the center of each $C{\bullet}C_H^+$ base pair and two between the central C4–C4 base pairs. Many close van der Waals contacts between sugars give rise to the strong inter-residue H1′–H1′, H1′–H2″ and H1′–H4′ nuclear Overhauser effects (NOEs). The 5′ phosphates of C4–C4 are above the bases and the C3–C3 phosphates below. Protons C3 H1′ and C4 H2″ are separated by only 2.2 Å. (b) Sequence of the immobile junction, J1. The molecule consists of four 16-mer deoxynucleotide strands labeled with arrowheads at the 3′-OH termini. In this study, the 5′ termini are unphosphorylated. In the text the duplex branches (''arms'') are numbered counterclockwise with arm 1 at the left. Note that three arms (1, 2 and 4) contain three AT base pairs, whereas arm 3 contains four. The octameric duplexes correspond to each of the arms of this structure, and also lack 5′ phosphate termini. (Reproduced by permission of Nature, Inc. from K. Gehring, J. Leroy, M. Gueron, *Nature (London)*, **363**, 564 (1993) and of John Wiley & Sons from L.A. Markey, N.R. Kallenbach, K.A. McDonough, N.C. Seeman, K.J. Breslauer, *Biopolymers*, **26**, 1622 (1987). to a quadruplex configuration (Figure 10c).[18–20] Long stretches of self-complementary G-rich DNAs form tetrad structures called ''eclectic DNA''.[11,18]

3.4 Higher Order Structures

The complexity of DNA structure increases in cruciform DNA (Figure 9b), immobile junctions (Figure 11b)[26] and Holliday junctions (Figure 12).[3] Seeman et al. have made and characterized a cubic DNA complex, built from segments of designed structural components comprised of rigid motifs (reported in[27]). This general field is being investigated intensively in the context of producing molecular machines, such as a nanodevice with rotating arms that interconverts between two structural states via B–Z and Z–B structural transitions.[27]

Cruciform DNA is composed of two DNA strands that have a special arrangement of complementary duplex DNA sequences called ''palindromes''. A cruciform forms when duplexes form at both ends while the two intervening strands become unpaired and loop out (Figure 9b). These strands then pair intramolecularly to form two separate hairpins (stem–loops), located external to the two flanking duplexes, forming a molecular cross.

Immobile junctions are composed of four strands which each form a duplex with two strands simultaneously, including pairing between the first and fourth strands to form a cross (Figure 11b). The junction residues form one or more mismatched base pairs.[26] An immobile junction is converted into a cruciform by covalently closing two of the four duplex segments to form hairpin loops. Immobile junctions were designed to understand Holliday junctions, a hypothetical structure proposed to form in the course of genetic recombination.[3] Immobile junctions are structurally constrained and do not ''slip'' to different pairings. The sum of stabilizing enthalpy contributions due to duplex formation in the arms approximately equals that of the junction.[26] In contrast, Holliday junctions must move freely to produce the paranemic junction, the structure formed when two duplexes intermingle during genetic recombination. In this case, enthalpies (ΔH) of both the arms and junction must be nearly zero to ensure that zipping is facile. This process is mediated by the recombinase proteins.

The recently discovered e-motif has been associated with triplet repeat expansion diseases such as Fragile-X syndrome and Huntington's disease, one of which causes approximately 20% of juvenile-onset retardation. The syndromes are attributed to overproduction (''expansion'') of triplet repeat sequences, yielding long fragile chromosomal domains. The problematic sequences were found to form hairpins containing distorted helices in vitro. This led to the proposal that such structures also form in the lagging strands of replication forks in vivo.[24] Polymerase slippage, promoted by hairpin formation, is thought to produce the structural instability and disrupt functions.[28,29] Cytosines flip out and away from the central axis of the helix, especially in sequences that

Figure 12 Holliday model of general recombination. First, nicks are introduced into a homologous region of each sequence. Subsequent strand invasion, DNA cleavage at the cross-over junction, and sealing of nicked strands results in exchange of the ends of the chromosomes. (Adapted from Prentice-Hall from L. Moran, K. Scrimgeour, H. Horton, R. Ochs, J. Rawn, *Biochemistry*, Prentice-Hall, Upper Saddle River, NJ, 26–25, 1994. Copyright © 1994 Prentice-Hall, Inc.)

accommodate C•C_H^+ base pairs. These extrahelical bases stress the phosphodiester backbone, distort the helix and induce hairpin formation. The two extrahelical bases fold symmetrically into the minor groove but do not form a base pair. [Note: an analogous ''base flipping'' mechanism leads to enzymatic methylation of C C5 atoms in duplex DNAs.[24]]

4 RNA STRUCTURE

Structures formed by RNAs and DNAs differ by the presence and absence of the C2′-hydroxyl, respectively. Hydroxide ions in basic solutions catalyze hydrolysis and cleavage of the phosphodiester backbone of RNA.[30] Hydroxide removes the hydrogen from the 2′-OH, producing an oxygen anion which then attacks the adjacent phosphate phosphorus, thereby eliminating the rest of the chain. Hydroxides are in solution and bound as inner- and outer-sphere ligands to divalent cations, a common source of catalytic activity in RNA reactions.

4.1 Duplex Structures

The most common duplex form maintained in RNA is similar to the right-handed A-form found in DNA. RNA can also form a left-handed conformation in high temperatures and salt concentrations, as well as in low hydration conditions.[31]

Both DNAs and RNAs form stable hairpins, but they are more prevalent in natural RNAs than in natural DNAs. They form when two sequential complementary regions of a strand fold together to produce a double-stranded region, terminated by one looped end and a duplex with either a blunt end, dangling strand or two extending strands (Figures 5a–d, 9b and 13a and b). In most biological examples, the free strands emerge from the duplex and continue into other strand domains. Lone hairpins have been extracted for study by researchers to assess their stabilities, structures and other properties. This general approach has its drawbacks but has led to the determination of many structural details that could not be obtained with their full-length counterparts. DNA cruciform structures contain two hairpins (Figure 9b).

RNAs can also form three- and four-stranded structures, with properties grossly similar to those of the analogous DNAs.[11,12,16,32]

Figure 13 (a) The proposed secondary structure of the 1542 nucleotide *E. coli* 16S rRNA based on the comparison of sequences from different species under the assumption that this secondary structure is evolutionarily conserved. The flower-like series of stems and loops forms four domains that are indicated by Roman numerals. The placement of certain features with respect to specific ribosomal proteins and the entire 30S ribosomal subunit are indicated. (b) The sequence of *E. coli* 5S rRNA showing its proposed secondary structure. (Reproduced by permission of John Wiley & Sons from D. Voet, J.G. Voet, *Biochemistry*, John Wiley & Sons, New York, 916, 1990.)

4.2 Substructural Components

Complex RNA structures are described in reference to its substructural components (Figure 5a–d). These substructural components form interesting three-dimensional structures that are important for binding and protein recognition. One very common substructural component is the loop. The stability of hairpins and loops

depends on the size of the loop and number of bases included; those with more negative enthalpic (ΔH) and entropy-dependent contributions ($-T\Delta S$) to the overall Gibbs free energy (ΔG).[1,7,30] Large internal loops, composed of two strands with (ostensibly) unpaired nucleotides, are thought to be essential for protein recognition. The smallest stable internal loop could be composed of a single-base mismatch.

Base mismatches can also produce bulged RNA (Figure 5a–d). Molecules with mismatches are less stable than those without mismatches; however, some mismatches are more stable than others.[8] As expected, stabilities of mismatched base pairs are often dependent on the surrounding stacked bases. Pyrimidine•pyrimidine base pairs are generally less stable than purine•purine base pairs. For example, the G•A, U•U, and C•C_H^+ base pairs are much more stable than G•G, C•A, C•U, A•A or C•C pairs. The U•U mismatch is stabilized by hydrogen bonding between complementary imino form nucleobase functional groups.

In an internal bulge (Figure 5a–d), one or more unpaired bases exist on one strand, sometimes stacked between the two flanking base pairs; in others, the base is excluded from the helix to produce a moderate deformation (it ''flips out''). The fate of the unpaired base depends on the surrounding sequences; pyrimidines tend to move away from the axis, whereas purines can remain extrahelical or intercalate, depending on the context and solution conditions.[7,30] Phosphates in bulged strands are extremely close together, producing an anionic domain. In one example, the anionic charge of the closely grouped phosphate oxygens interacts with two Mg^{2+} ions to stabilize the bulge.[33] Bulges and loops are similar in that they are more constrained than single-stranded molecules. As hairpin loops increase in size, their constraints decrease progressively toward those of lone strands.[7]

Figure 14 (a) Nucleotide sequence of yeast $tRNA^{Phe}$ folded (left) into secondary ''cloverleaf'' and (right) into tertiary ''L-shaped'' arrangements. Invariant bases in class I tRNA are indicated by circles; those which are semi-invariant are enclosed in parentheses. WC-type hydrogen bonds in stem regions are marked by dots and the G•U ''wobble'' pair (G4•U69) by a small circle. The number of nucleotides in variable loop V and in α and β regions can vary, depending on the tRNA species. Bases forming tertiary base–base hydrogen bonds are connected by thin lines. Note that most of the invariant and semi-invariant bases are positioned in the middle and hinge regions of the ''L'' and involved in tertiary hydrogen bonds which, together with base stacking, illustrates which parts of the ''cloverleaf'' join together to form the two legs of the L. (b) Illustration of base-pairing and stacking interactions in yeast $tRNA^{Phe}$. Base pairs stabilizing secondary and tertiary structure are drawn as bent or fused slabs or by connecting two slabs with rods. Invariant and semi-invariant bases cluster in anticodon loop, CCA end of acceptor stem, and at outer corner and hinge regions of the ''L''. Note stacking of bases 34–38 in the anticodon loop, consisting of the anticodon 2′-*O*-methylguanine (G_m)43–A35–A36. [Circled letters a–g indicate where base pairs and triplets displayed in Figure 15-4 in the original publication are located.] (c) Schematic representation of the π_3-turn situation in anticodon and T loops of yeast $tRNA^{Phe}$. Sugars and phosphate groups are simplified as large and small spheres, respectively; bases as slabs; base pair interactions by a bar; H represents hypermodified base. Semi-invariant and invariant bases are stacked with the base pair at the top end of the loop, and the bases at the bottom of the anticodon loop are again stacked with the bases to the right. Phosphates are actively engaged in the turn and form hydrogen bonds and stacking interactions. (Reproduced by permission of Springer-Verlag from W. Saenger, *Principles of Nucleic Acid Structure*, Springer, Berlin, 332, 335, 339, 1984. Copyright Springer-Verlag 1984.)

Figure 14 (*Continued*)

4.3 Higher Order RNA Structures

Substructural components interact to form higher order structures. For example, the amino acid acceptor stems and anticodon stem–loops of tRNAs form an L-shaped tertiary structure when the other two stem–loops fold together to form a kind of ''glue'' that stabilizes the ''joint'' region of the L (Figure 14a–c).[1] Structure is one of the defining components of function and is intimately related to sequence. Strands composed of different sequences can sometimes form similar secondary structures. In fact, in a few known cases secondary structures can adopt similar tertiary structures.[7]

The anticodon bases of tRNA jut away from the rest of the loop and can interact with ligands (Figure 14a–c). The anticodon loop bases can convert between the ''3′-stacked'' and ''5′-stacked'' structures, in which the nucleotides in the loop align above either the 3′- or 5′-terminal strand of the attached duplex stem. Although the anticodon region of tRNA is single-stranded, its bases stack and thus stabilize the extended exposed face of the trinucleotide, which facilitates codon recognition and decoding. Another stabilizing structural component of the anticodon is the U-turn, in which U33 interacts with the phosphate of residue U37 (Figure 14c). A wealth of different base assemblies occur in tRNAs, forming a large percentage of our lexicon of RNA substructural components.

Pseudoknots are a common higher order structural motif in natural RNAs. In these structures, the loop of a hairpin binds to a complementary sequence adjacent to the sequence that forms half of the stem of the hairpin (Figure 15a and b).[7,34] Unlike U-turns, pseudoknots do not occur in tRNAs. The ability of the pseudoknot structure to bend is affected by steric hindrance between nucleotides that comprise the two entangled loops. The structure is compact, not elongated, resembling a moderately extended globular protein. Because the pseudoknot is comprised of two smaller hairpin substructures, the RNA molecule can form two different hairpins with either a 5′- or 3′-terminal ''dangling end'', depending on their respective free energies (Figure 14a–c).[7] Transitions between these two structures depend on both base sequence and salt concentration.

Pseudoknots are thought to regulate transcription, possibly controlled by cation concentration fluxes, protein

Figure 15 Pseudoknot formation. (a) Sequence of the oligonucleotide. (b) A pseudoknot is formed when a few bases outside the hairpin formed at the 3′ end of the oligonucleotide pair with a few bases within the loop of the hairpin to form a second stem and loop region. Stem I is denoted in black and consists of three base pairs. The five base pairs of stem 2 are hatched. Loop I bridges stem 2 across the major groove of the RNA helix. Loop 2 crosses stem 1; since this loop bridges the minor groove this distance is further than that crossed by loop I. (c) Similarity between the structures of the [tRNA anticodon•codon] complex and mouse mammary tumor virus RNA frameshift pseudoknot. (Reproduced from J.R. Wyatt, J.D. Puglisi, I. Tinoco, Jr, *Bioessays*, **11**(4), 104 (1989). Copyright © 1989 John Wiley & Sons, Reprinted by permission of Wiley-Liss, Inc., a division of John Wiley & Sons, Inc., and by permission of Harcourt Brace Inc. from L.X. Shen, I. Tinoco, Jr, *J. Mol. Biol.*, **247**, 974 (1995).)

recognition or both.[7] They can mediate protein recognition by forming structures resembling tRNA acceptor stems. For example, this occurs at the 3′-termini of some plant viral genomic RNAs (e.g. tobacco yellow mosaic virus). In this case, two different secondary structures, viral pseudoknots and tRNA stems, form similar tertiary structures. The 3′-terminal hydroxyl group of the viral RNA is aminoacylated by the ''cognate'' aminoacyl tRNA synthetase, forming a protective genomic ''cap'' that prevents exonucleolytic digestion.

Ribosomal recognition depends on sequentially binding similar, but subtly distinctive, tRNA anticodon and mRNA codon structures formed as the mRNA is processed by the ribosome and read by tRNA. This normal process can be subverted in several known ways. For

example, a suppressor tRNA skips (reads through) a stop codon by inserting an amino acid (commonly tyrosine) into the nascent protein chain instead of terminating protein synthesis.

In another situation, translating ribosomes can pause when the mRNA is allowed enough time after its transcription to form a certain stem–loop structure. The time-frame of the pausing event depends on the stability of this hairpin. The phenomenon is the basis for translational attenuation, in which amino acid starvation results in the absence of that aminoacylated tRNA. During this duration, one type of folded stem–loop motif forms and translation continues.[2,3] To ensure that the anabolic enzyme needed to produce this amino acid is made, sufficient ''charged'' aminoacyl tRNAs must be available to translate the leader sequence codons. If stalling lasts long enough, an alternatively folded hairpin forms and translation is aborted. The amino acid concentration, titrated by the time-frame of transcription and movement of tRNAs through the ribosome, determines whether protein is made or not. This mechanism illustrates the tightly linked interplay between two different folded mRNA structures and the initial unstructured transcript. Their energetics and relative folding time-frames determine finally whether it is translated or abandoned.

Translational frameshifting occurs when ribosomes pause preferentially at internal sites on the decoding mRNA strand. When a translating mRNA forms a pseudoknot, the ribosome pauses much longer at that site. This increases the degree of ''slippage'' in base pair alignment between tRNAs and the reading frame of the mRNA, making a frameshift possible. One such example occurs during translation of the mouse mammary tumor virus genome, in which alternative viral proteins are encoded in different overlapping reading frames (Figure 15c).[22] Pseudoknot formation produces a (−1) nucleotide frameshift and, as a result, alternative proteins.

The recently identified A-platform structure was determined by X-ray crystallography (Figure 16a–c).[21,33] This large RNA fragment forms a catalytically active subregion which was extracted from the much larger *Tetrahymena* Group I intron structure. This fragment is important because the residues in the vicinity of the A-rich bulge are essential for ribozyme activity.[20] The A and flanking residues bind a string of Us in a second domain formed by distant primary sequence residues. This ''docking'' interaction links distantly separated sequences via base pairing. A ''GNRA tetraloop'' subfragment[35] binds the A-platform, termed its receptor, and as a result produces a tertiary structural motif composed of a stem fragment ''super-looped'' back on itself and adhered to a distant stem with an intervening bend region. The platform undergoes a large conformational change in the absence of this tertiary interaction. The A-platform is stabilized more by base stacking forces than hydrogen bonding, but both contribute.[21]

Figure 16 (a) Schematic secondary structure of the P4–P6 domain, with adenosine platform in bold. The noncanonical base pair below each platform is also shown. (b) Location of adenosine platforms in the crystal structure. The structure is shown in the same orientation as that of (a); adenosines of the platforms are highlighted in blue and green (in the original article), while the backbone positions of the wobble base pairs below the platforms are indicated in red. Blue adenosines are accessible to dimethyl sulfate (DMS) in the presence and absence of the docking partner associated with the platform; green adenosines (in the original article) are protected from DMS modification when the docking partner is present. (c) Another view of the crystal structure, rotated 90° about the long axis of the molecule. The conserved core region is to the right in (a) and (b) and the core faces the reader in (c). (Reprinted with permission from J.H. Cate, A.R. Gooding, E. Podell, K. Zhou, B.L. Golden, A.A. Szewczak, C.E. Kundrot, T.R. Cech, J.A. Doudna, *Science*, **273**, 1697 (1996). Copyright 1996 American Association for the Advancement of Science.)

Many of the stem loop sequences in known RNA folds contain consensus GNRA tetraloop sequences.[2,3,35,36] Ribosomal RNA secondary structures have been predicted from sequences obtained from organisms spanning a broad range of phylogeny. Sequence requirements for the unique stabilization are very specific and clearly linked to binding interactions between the participating residues. The initial G base and final A phosphate form a hydrogen bond and the N7 atom of the third purine (R) forms a hydrogen bond with the sugar hydroxyl hydrogen at the N position, which can therefore be any nucleotide. The second nucleotide is not specifically involved in stabilizing the structure. These more stable tetraloops are thought to play a key role in the tertiary folding of large RNAs. Reverse transcriptase stop sites often contain this sequence.

Another unique example of RNA tertiary structure is formed when two hairpin loops dock to produce ''kissing hairpins'', the evolutionarily conserved motif formed by genomic human immunodeficiency virus (HIV) RNA.[37] The HIV genome is comprised of two identical positive sense RNA strands. Hairpin loops at the 5′ ends of each molecule promote genomic dimerization in vitro and are required for viral packaging in vivo. RNA quadruplex formation by two condensed HIV genomes has also been proposed to mediate viral packaging.[16]

The hammerhead RNA motif is functionally and structurally similar to the Group I intron fragment.[33,38] The three stems in the hammerhead ribozyme form a three-way junction (Figure 5d); the nucleotides all maintain the *anti* configuration. Hammerhead RNA is thought to mediate RNA processing, catalyzing specific cleavage and maturation of the initial RNA transcript. Structural formation and enzymatic activity require the presence of divalent cations, primarily Mg^{2+} in vitro, although other cations (and some of the transition and posttransition metals) function in a similar fashion. They are thought to act as Lewis bases, increasing the local OH^- concentration and possibly directing reactants into the precise tertiary structure(s) essential for cleavage.[38]

Hammerhead RNA cleavage has been characterized using Michaelis–Menten kinetics. Reaction rates depend on reactant and product concentrations and pH values.[38] Cleavage does not occur below pH 5, most likely because required nucleotides are protonated. The reaction rate increases until pH 7 is reached, then decreases rapidly.[7] Cleavage does not occur at higher temperatures. Since proper tertiary structure formation is so essential, the destabilization that occurs at higher temperatures probably short-circuits the reaction mechanism.

5 ENERGETICS

The numerous examples described so far clearly illustrate that the structures, functions and energetics of nucleic acids are intricately linked. Many techniques and strategies have been developed to study these relationships quantitatively, each emphasizing different aspects of detected properties and/or functional groups of the nucleic acid under investigation. These structural entities range from individual bonds to moderately sized complexes (e.g. duplexes) to large structures, such as superhelically stressed plasmid DNAs. One strategy used to study these problems is to ''divide and conquer''. Studies define facets of a problem in a piecewise fashion in the hopes of using the resulting information to solve problems involving the structure within its overall context. As previously outlined, the smallest complex substructure is the base pair. Adjacent base pairs affect the stability of each other. Nucleotides on both sides contribute when a base or base pair is embedded within a duplex, producing a sequence-dependent synergism. This additivity is called and modeled mathematically as the ''nearest neighbor effect''.

Interbase orbital overlap is optimized within the constraints otherwise available to the aggregated domain as a result of the hydrophobic effect. Dipole–dipole London dispersion forces also participate in stabilization, but knowledge regarding relative contributions is not precise. Theoretical calculations support the expectation that large subdomains form synergetically. Quantum mechanical energies and van der Waals forces require including structures up to at least a 15 Å distance away from a particular atom to achieve self-consistency. Individual base pairs affect those around them and vice versa.

5.1 Thermodynamic Characterization

The most common method to characterize the energetics of nucleic acids in the context of structure involves measuring equilibrium thermodynamics. The net spontaneity of a reaction is characterized by ΔG, but only if the mechanism is rapid compared with the scan rate of the melt temperature-ramping process. The familiar result is that more stable interactions have more negative free energies. In the usual vernacular, the process (e.g. structure formation) is more spontaneous. An important characteristic of ΔG is its logarithmic proportionality to the equilibrium constant and its dependence on temperature, characterized by the fundamental equations [Equations 1 and 2].[30,39–41] Reactants must attain enough energy to pass the transition state to form products.

$$\Delta G = \Delta H - T\Delta S \tag{1}$$

$$\Delta G = -RT \ln K \tag{2}$$

Both ΔH and ΔS contribute significantly to the net ΔG of many duplex denaturation–renaturation reactions. These parameters characterize sequence-dependent stabilities of intra- and intermolecular nucleic acid complexes. Their relative contributions demonstrate many subtleties regarding interdependences between molecular energies, structures and solvent components. In many cases, they give important insights into the relations between structures and functions. In this account, we generally only list qualitative comparisons or trends found, especially focusing on how the parameters depend on the relevant variable(s) (but many quantitative results are cited in the Further Reading).

Base stacking is one of the predominant driving forces behind the maintenance of nucleic acid structure. The partially hydrophobic bases stack with one another to minimize interaction with the surrounding solution and each other (Figure 17).[1,6,42] As expected, the more hydrophobic purines stack with more stability than pyrimidines. Stacking ability depends on the electron distribution of the rings and their exocyclic components. Disrupting the stacked structure is usually accomplished by raising the solution temperature, leading to thermal denaturation (melting). Less stacked or unstacked random coil structures are rarely found, except at elevated temperatures or under relatively destabilizing conditions (i.e. in lower polarity solvents or in 7 M urea).

Hydrogen bonds also play a major role in stabilizing nucleic acid structure.[1] In fact, helix structures literally revolve around them. Exocyclic protons and lone-pair electron components on opposing bases form these complementary interactions. To a reasonable approximation, relative stabilities and flexibilities of different structures are determined by hydrogen bonds. Their strength depends critically on interatomic distance and orientation, with linear alignment of the three atoms being optimal. Since G•C base pairs have three hydrogen bonds, they are stronger than A•T or A•U base pairs, which only form two. Relative stabilities correlate with the number of hydrogen bonds. Since both G and C are more hydrophobic than A and T (and less hydrophobic U), stabilization is also correlated with less polar components.

Figure 17 (a) Base-pair and base-step parameters of nuclei acid double helices. The structures of double-stranded nucleic acids are defined by the relative conformations of two adjacent base pairs in a base step (e.g. helical twist, roll, tilt, rise and slide) and the relative conformations of the bases in a base pair (e.g. the propeller twist). (b) Illustration of ''Calladine's rules''. (i) Adjacent G•C base pairs in a DNA double helix, with positive propeller twist, display sequence-dependent interactions between guanines on opposite polynucleotide chains. (Top) The sequence pyrimidine-(3′,5′)-purine leads to clashes in minor grooves (open arrow), whereas the purine-(3′,5′)-pyrimidine sequence (middle) causes clashes in the major groove. Clashes can be avoided by reduction of propeller twist, opening up the roll angle θ_R (bottom), reduction of helical twist (t) shown in (c), or shifting base pairs such that the purine (guanine) is pulled out of the helical stack [shown in (ii)]. (ii) The purine–purine clash displayed in (a) can be reduced by shifting the G•C base pair laterally, which pulls the G out of the helical stack (arrow). In order to maintain similar helical P–P distances, sugar puckers are changed, yielding a larger δ angle for purine and a smaller one for pyrimidine. Associated with these changes are χ rotations, as required for the ''autocorrelation principle'' [section 11-2 in the original publication]. Increase of helical twist from 36° to 45° (top) shortens the distance between N3 atoms in the minor groove (top), whereas reduction to 27° (bottom) widens this distance. If coupled with a positive propeller twist, N3 atoms in the top base pairs (heavy lines) move down (indicated by minus signs), those in the bottom base pairs (heavy lines) move down (indicated by minus signs) and those in the bottom base pairs (light lines) move up, leading to unfavorable N3–N3 clashes. These clashes are diminished by helical untwisting to 27° (bottom). (Adapted from Prentice-Hall from K. Van Holde, W.C. Johnson, P.S. Ho, *Physical Biochemistry*, Prentice-Hall, Upper Saddle River, NJ, 56, 1998. Copyright © 1998 Prentice-Hall, Inc., and of Springer-Verlag from W. Saenger, *Principles of Nucleic Acid Structure*, Springer, Berlin, 254, 255, 1984. Copyright Springer-Verlag, 1984.)

Figure 17 (*Continued*)

Enthalpy changes can be determined indirectly via Van't Hoff analysis or directly using calorimetric approaches. Van't Hoff approaches monitor the properties of a certain substructure as they change (Figures 18a and b, 19a and b and 20). One must find conditions suitable to measure the equilibrium constant of a reaction as a function of temperature. The melting behavior of nucleic acid complexes is sensitive to its strand number, its molecularity (n). The Van't Hoff enthalpy (ΔH_{VH}) is calculated using Equation (3):[40]

$$\Delta H_{\mathrm{VH}} = (2 + 2n)RT_{\mathrm{m}}^2 \left(\frac{\partial \alpha}{\partial T} \right)_{T - T_{\mathrm{m}}} \qquad (3)$$

The "melting temperature" (T_{m}) refers to the temperature at which the concentrations of single (melted) strands and paired structures are equal, the midpoint of the equilibrium, and α is the extent of the reaction. The term $T - T_{\mathrm{m}}$ indicates the temperature range studied to probe the reaction equilibrium. For species with $n > 1$, the equilibrium poise is strongly dependent on the strand concentration, adding more shifts the poise toward the products.[32,39,40] Increasing the temperature dissociates the strands. The breadth of the $(1 - \alpha)$ vs T curve is an indication of the degree of cooperativity of the transformation. Zipper models capture the image well; initial pairings facilitate subsequent pairings (positive cooperativity). Both duplex assembly and melting are relatively (positively) cooperative. Increased ionic strength and cationic polyamines and proteins increase the cooperativity.[39,43,44]

5.2 Calorimetric Determination of Enthalpies

Calorimetric methods also provide an approach to obtaining information about the enthalpy changes associated with structural transformations, ligand binding, etc. The change in heat capacity (ΔC_{p}) is determined calorimetrically by scanning across the same range of temperatures used for the UV spectral melt data acquisition, then integrating the resulting derivative plot [Equation 4]:[40]

$$\Delta H^{\circ} = \int \Delta C_{\mathrm{p}} \, \mathrm{d}T \qquad (4)$$

The differential scanning calorimetry (DSC) apparatus scans through the temperature range encompassing the structural transition slowly enough to ensure that the strands equilibrate at each intermediate temperature.[39] DSC enthalpies should be equal to those calculated by

Figure 18 (a) Schematic representation of a thermally induced transition from a fully base-paired and base-stacked double helix to two unpaired and unstacked single strands. (b) (i) Schematic of an optical density (O.D.) vs temperature profile (a UV melting curve) showing the hyperchromic effect associated with a transition from a base stacked (helix) to an unstacked (coil) state. (ii) A derived melting curve showing the fraction in the coil state $(1-\alpha)$ as a function of temperature. The two figures together illustrate how the experimental absorbance vs temperature profile can be converted into a $(1-\alpha)$ versus temperature melting curve. van't Hoff analysis if one applies the correct molecularity. For example, n was calculated from calorimetric and spectroscopic data obtained with the quadruplex DNA formed by $d(G_2T_5G_2)$ in 1 M NaCl.[17]

Entropy is related to the degree of disordering open to a molecule, which is modeled mathematically by enumerating the number of possible statistical variations of a "system" and stipulating the population distributions among them. These distributions could characterize a set of different molecular conformations, orientations or interactions between functional groups or more than one molecule. They could also include their interactions with ligands or solvent.

Water contributes in a particularly important way to entropy changes of biomolecules.[1,45,46] The stability of nucleic acid structural aggregates is strongly influenced by hydrophobic interactions involving buried and exposed residues and the surrounding solvent. The energy associated with the cage of water molecules surrounding the structure is governed by both entropy and enthalpy; the dominant contribution changes with increasing temperature. At temperatures ($\lesssim$60 °C), hydrogen bonds (enthalpic contributions) interconnect the surrounding

H_2O molecules and ''encage'' the more hydrophobic nucleic acid, forcing it to fold into the native structure. When the temperature is increased above ca. 60 °C, vibrational fluctuations overcome the hydrogen bond energies, the cage H_2O molecules dissipate and the nucleic acid denatures. Enthalpic contributions to folding energies dominate at lower temperatures; the ΔS associated with H_2O randomization and release dominates at higher temperatures. A similar situation governs equilibria associated with protein folding and membrane assembly.

5.3 Spectroscopic Techniques

As discussed previously, UV absorbance spectroscopy is commonly used to study the thermal denaturation behavior of nucleic acids (Figures 18–21).[1,30,39] This method allows one to study temperature-dependent dissociation (melting) and association (hybridization) behaviors, conformational changes and ligand binding. The large extinction coefficients of the nucleobases allow one to perform studies with relatively low sample concentrations (micromolar to millimolar). The molar extinction coefficients of individual bases decrease when the bases stack, a phenomenon called the hypochromic effect (Figures 18 and 19). UV spectroscopy allows one to monitor the course of temperature-dependent transitions by studying the ratio of stacked to unstacked bases. The total absorbance of the disrupted structure is larger than the sum of the absorbances of each individual nucleotide. Denaturation by melting the stacked bases produces an increase in the absorbance at 260 nm, allowing one to obtain quantitative energetics, usually by studying the concentration dependence of T_m (Figure 20).

The sequence of a nucleic acid influences the stability of the strand in a base-paired secondary structure. Contributions to stabilization by stacking interactions, resulting from different nearest neighbor free energies, determined for a set of DNA sequence variants, are shown in Table 1. Similar data obtained with RNA variants are shown in Tables 2 and 3. These nearest neighbor stacking energies provide a method to estimate the stabilities of RNA or DNA duplexes (Figure 21). This information has been used extensively to predict the most energetically likely secondary structures (e.g. Figures 13–16). While these predictions are useful, they are only approximations and must be interpreted cautiously. For example, slow reaction kinetics can lead to invalidation of the equilibrium assumption upon which the analysis is based.

Secondary structures are also predicted from evolutionary sequence conservation data. Biological sequences remain similar over time and large portions of genomes often exhibit cross-species similarities. Therefore, it is inferred that they maintain similar structures. Promoter region sequences of genes, GpC islands, centromeres, telomeres and other repetitive sequences (SINES, LINES, Alu sites) are often evolutionarily conserved.[4,47] Slight changes in sequence (and as a result structure) may produce changes in gene expression or RNA-mediated functions. Mutations do not typically affect the functions of DNAs, RNAs or their encoded proteins. Although usually quiescent, the mutant RNA or protein structure may contain interactions or adopt structures with severely compromised functions, resulting in dire health consequences. Many of the modern approaches to studying disease revolve around the protein aspect of this

Figure 21 Application of data to evaluate a possible secondary structure for a 55-nucleotide fragment from R17 virus. Overall ΔG at 25 °C is -21.8 kcal mol^{-1}. $^{5'}$TA•AT$^{5'}$		−3.82

problem, in part because much is known about protein structures, functions and the effects produced by mutations. Much less is understood about nucleic acids, although the situation is improving rapidly. One cannot overemphasize the key linkage between mutations, structural consequences and altered functional viabilities. This is used to advantage by some error-prone viruses (e.g. HIV), which mutate rampantly, and in the process ''learn'' (adapt) to out-fox antiviral pharmaceutical therapies.

Nucleotides at specific positions of a structure are evolutionarily conserved in order to preserve the secondary and tertiary structures in which they participate. Covariant mutations occur when two paired bases in the helix of one wild-type secondary structure are replaced by the inverted base pair in another. This swaps the flanking bases, which can change the stability, but preserves the base pair. The second mutation occurs to compensate for the lost interaction produced when the first mutation occurs.

A more complicated absorption property of nucleobases, their interaction with circularly polarized UV light, has been used extensively to study nucleic acid structures and interconversions. The circular dichroism (CD) spectrum, obtained with a spectropolarimeter, is a plot of the difference in absorbance of negatively (right) and positively (left) circularly polarized light as a function of the wavelength range studied.[1,45,48] This difference is very sensitive to the detailed chirality of stacked and interacting base assemblies and their structural changes. Many structural transformations, ligand binding reactions and chemical modifications (e.g. with covalently reactive mutagens) have been characterized.[49] Nucleic acids become more chiral when a helix forms and less so when it denatures. When information can be acquired using other techniques that yield structures [i.e. molecular coordinates; e.g. X-ray crystallography or NMR] or about specific bond motions (e.g. NMR, Raman scattering spectroscopy), CD results can be used to great advantage to study changes between two or more previously characterized states. The more qualitative CD technique is sensitive and easier, allowing one to characterize a much more extensive range of variables.

IR and Raman spectra are sensitive to vibrational motions of specific functional groups and are used to study the stretching and bending frequency modes of molecules. IR and Raman methods allow one to study interactions between functional groups, e.g. to monitor the formation and loss of hydrogen bonds. Bond formation and dissociation change the frequency of the absorption (or scattering) peak, allowing detailed analysis of bonding changes in nucleic acid and between them and proteins, ligands, etc.

Raman and IR spectra provide complementary information about the active types of vibrational modes predominant in the absorptive functional groups being monitored.[1,45,48] The bond is the chromophore. For example, Raman spectroscopy was used to study the assembly and disassembly of DNA quadruplexes formed

by one or two strands, demonstrating that the mono- and bistranded complexes depend differently on Na^+ and K^+ concentrations.[15] Raman scattering works better than IR to characterize most aqueous samples. Atoms can move in a symmetric scissors motion (toward and away from each other within the plane formed by the three atoms). Asymmetric wagging fluctuations (of the two bonds with respect to each other) are also possible. In the symmetrical motion analogy, one scissor blade can either close when the other closes or opens simultaneously. In the asymmetric case, the motions of the bonds occur in two planes that are skewed with respect to each other and at frequencies that are not correlated in time. Only symmetrical shifts are active (observed) using IR spectroscopy. Molecules with complex conformational constraints rarely maintain perfectly symmetrical motions, so Raman scattering can be used to study functional groups that fluctuate predominantly via symmetrical motions, but also have these imperfect symmetrical stretches. Raman spectroscopy is relatively sensitive and has a key advantage relative to IR. Peaks normally observed using IR are obscured by the dominant symmetrical stretch motion of solvents such as water. Water is less Raman active and can usually be filtered out using deuterium oxide, allowing visualization of most functional group peaks. Structures and dynamics of nucleic acids have been characterized in systems ranging from nucleotides to duplexes to viral genomes in packaged virus particles. Interactions, motions and assembly–disassembly phenomena have been elucidated.

NMR has also provided a wealth of structural and dynamic information about nucleic acids. ^{1}H-NMR has been used to study protons; ^{31}P-NMR provides information about the backbone phosphorus atoms and connected structures.[49–53] ^{13}C-NMR has been used to study skeleton carbons; ^{15}N-NMR has yielded information about amino and imino NH groups. All of these isotopes, in addition to deuterium, are used in various multidimensional NMR experiments to assign peaks by characterizing through-bond interconnectivities. Spectroscopic relaxation studies with ^{1}H-, ^{13}C-, ^{31}P- and ^{15}N-labeled molecules have been used to probe fluctuational motions, their spatial magnitudes and timescales. The ^{1}H–^{1}H nuclear Overhauser effect (NOE) and scalar J-coupling methods allow one to determine the frequencies (chemical shifts) of peaks of specific hydrogen atoms and determine calibrated distances between these assigned atoms. Three-dimensional structures are determined by reconstructing spatial connectivities between neighboring hydrogen atoms.

Problems associated with simultaneously stipulating structure and the ranges and frequencies of molecular motions, when many different types of motion are occurring, complicate calculating structures. Full matrix data analysis techniques and molecular mechanics/dynamics simulation protocols have been developed to do so, but information is limited so far (some examples are described in the Further Reading section).

5.4 Electrophoretic Techniques

Electrophoresis separates molecules, structures and/or complexes based on different charges and size-dependent properties. Larger molecules and plasmids are separated on agarose gels; moderately sized and smaller molecules are resolved on polylacrylamide gels. The electrophoretic mobility decreases with the size (charge) of the negative nucleic acid backbone. High-percentage polylacrylamide gels (ca. 20%) can separate oligo- and polynucleotides ranging up to ca. 500 nucleotides in length, differing by only one nucleotide, termed single-base resolution in sequence determination. This has allowed the molecular characterization of many sequences, ligand binding sites, complex formation reactions, mutagen action scenarios and other reactions. The results are always based on how the process of interest alters the size and/or charge of the nucleic acid fragments under study. The chaotropic solute urea is typically used to denature nucleic acids in gels. Native structures and complexes have been studied extensively. For example, protein binding decreases the mobilities of bound nucleic acids, the basis of the mobility shift technique.[54]

Electrophoretic techniques have been used to understand the effects of superhelical stress on the supercoiling behavior of DNA. Supercoiled closed-circular plasmid DNAs are more mobile than relaxed plasmids because they are smaller hydrodynamic particles. Introducing negative supercoils while maintaining the B conformation introduces torsional strain; adding a single negative supercoil increases ΔG (at 25 °C) for duplex formation by about 38 kJ mol^{-1}. Thermodynamic stress is relieved by induction of Z-DNA and cruciform formation. Extremely large amounts of DNA are present in the small volume of the nucleus. The DNA packaging process requires a large amount of torsional stress.[55]

Such molecules have traditionally been modeled as ordered condensed double helices. Aged cells contain significant amounts of damaged aggregates. Nucleic acids are recycled when cells undergo apoptosis (programmed cell death), degraded by Ca^{2+}/Mg^{2+}-containing nucleases.

Electrophoresis has been used to determine how topoisomerases relax and induce torsional stress by catalyzing induction and/or relief of supercoiling. Topoisomerases are essential for DNA replication and transcription, since torsional stress must be relieved in order to unwind the double helix. Topoisomerase I relaxes torsional stress by cutting only one strand in duplex DNA and rotating the freely dangling ends in opposite directions around the axis of the uncut strand. Topoisomerase II enzymes (DNA gyrases) can introduce negative supercoils by introducing double-stranded breaks, then resealing the backbones. Since the number of rotations prior to resealing vary in a stepwise (integer) pattern, one obtains a family of discrete topoisomers. The individual topoisomers can be separated and the energies associated with their interconversions quantitated using a two-dimensional gel electrophoresis technique involving the use of the intercalative molecule chloroquine.[56,57]

Electrophoretic analyses of products generated using more traditional methods involving chemical reactivity and enzymatic recognition have also been used to determine how a broad range of intercalators affect the structure and energetics of DNAs and RNAs. Intercalation involves stacking of a planar aromatic molecule (e.g. ethidium bromide) between two base pairs, thereby increasing the length of double-helical DNA.[1] This distortion can result in mistakes in replication which may produce genetic mutations. Since intercalators relieve superhelical stress, the hydrodynamic volume of a plasmid increases, decreasing its electrophoretic mobility.

DNA can form higher order structured aggregates. One example of a noncytoplasmic, minimally soluble, DNA state forms when DNAs and RNAs packed inside viral particles to form condensed aggregates. Topological stresses in such situations are not well understood. Structures have been studied using low-resolution electron microscopy, low-angle X-ray scattering and Raman spectroscopy approaches. Model structures called P-DNA and ψ-type DNA have been developed based on CD, linear dichroism and CD scattering results. Left-handed Z-DNA duplexes can form multistranded, torus-shaped macroaggregates which have been characterized using electron microscopy.

Temperature gradient gel electrophoresis is another example of a method that can be used to determine the melting behavior of a nucleic acid structure. One determines the change in electrophoretic mobility of a structure produced by increasing the temperature. Samples are electrophoresed in two dimensions, through an increasing temperature gradient in the first, and through an electric field that separates molecules according to size in the perpendicular direction. For example, analysis of interactions between the P4 and P6 domains of the self-splicing Group I RNA from *Tetrahymena* demonstrated that tertiary structural folding is driven predominantly by ΔH, with a smaller $-T\Delta S$ contribution to ΔG.[58]

Continuous mixing analysis has been used to study equilibria between strands, a duplex and a triplex. Absorbance changes, due to continuous variations in strand number in populations containing two- and three-stranded complexes, were used to determine stoichiometries. Relative concentrations of oligo(A) relative to oligo(U) were varied from 1 : 10 to 10 : 1. The data led to the interpretation that two duplexes disproportionate to produce an [oligo(A)•oligo(U)] duplex at A/U $\approx$ 1 : 1 and an [oligo(A)•oligo$(U)_2$] triplex when the ratio is ca. 1 : 2.[32]

6 CONDITION-DEPENDENT STRUCTURAL TRANSITIONS

6.1 Cation Dependences

Nucleic acid structural transformations can be induced by changing the existing solution components, concentration, temperature, ligand binding and many other factors. Cation concentrations can strongly influence their stabilities by modulating melting rates and reactant–product equilibrium distributions. Atmospherically bound cations are relatively loosely bound to the anionic oxygens of the phosphodiester backbone [equilibrium dissociation constant (K_d) $\approx 10^3\,M^{-1}$]. Duplex dissociation is accompanied by cation (counterion) release. Counterion condensation theory[59] was developed to fit cation–nucleic acid binding isotherms (curves) measured using ^{23}Na-NMR. Fits require that only about 90% of the phosphodiester backbone charge (due to anionic oxygens) be neutralized to achieve thermodynamic equilibration. Duplexes have a higher negative radial charge density than individual strands. Because cations help neutralize the additional charge density, duplexes become favored and stabilized as the salt concentration is increased. The trend of increased charge density continues in proceeding to triplexes and quadruplexes. The surrounding cations are accompanied by H_2O molecules that are packed more densely than bulk H_2O, held within a Donnan sphere as a result of osmotic pressure (and other effects produced by dissolved osmolytes).

The right-handed B-form duplex poly[d(CG)$_2$] is converted to the left-handed Z-form with a transformation midpoint at ca. 2.2 M NaCl using strands in the micromolar range.[9] Placing bulky bromine atoms or methyl groups at the C8 atoms of guanines 8-bromoguanosine (br^{8}G) induces Z formation because the base swings about the glycosidic bond, relative to the sugar ring, from the B-form *anti* conformational isomer (conformer) to the *syn* structure. The B- to Z-DNA conversion also occurs upon adding 5 mM $MgCl_2$, but only if the Cs are methylated, poly[d(m^{5}CG)$_2$], illustrating a case of transformational induction mediated by two synergistic factors. The physiological $MgCl_2$ concentration is ca. 1–5 mM, but varies with organism and cell type. Cytidine methylation occurs naturally in many chromosomal domains in patterns that vary with cell-cycle phase and developmental stage dependent factors.[2,4,47] Correlations suggest that Mg^{2+} and m^{5}C may work to induce B to Z transitions in live cells under some circumstances.

The Z-form of RNA adopted by poly[r(CG)] is much more difficult to induce than Z-DNA. Z-RNA formation occurs in buffer at a transition midpoint of 6 M $NaClO_4$, a much more chaotropic salt than NaCl, and heating to ca. 40 °C. A solution of 4 M $MgCl_2$ in buffered 10% ethanol also works. Like DNA, the presence of br^{8}G induces Z-RNA formation; unlike DNA, 5-bromocytidine (br^{5}C) inhibits Z-RNA production. Molecular mechanics modeling analysis suggests that the difference can be attributed to steric repulsion between the C5 bromine atom and the 2′-hydroxyl, which is missing in DNA.[60]

Changing the type of cations and their concentrations and also the strand concentration(s) can profoundly affect the stability of quadruplex DNA. Guanine-tract-containing RNAs also readily form the quadruplex, e.g. a fragment from *E. coli* 5S rRNA (Figure 13b, ca. nucleotide 80).[16] Manipulating these factors can induce transitions from duplex to quadruplex and (under very specific circumstances) vice versa. Quadruplexes are stabilized by Group 1a monovalent cations in the order $K^+ > Na^+ > Rb^+ > Li^+$ and Cs^+ by binding in the center of the Gs, forming a cation spine down the central axis of the complex (Figure 10b). The distribution of products formed by two different quadruplex formation pathways, from two or four strands, can be varied by manipulating the total concentrations of strands, K^+ and Na^+. This phenomenon, the sodium–potassium switch, permits control over the predisposition to form alternative quadruplex structures from strand precursors by manipulating cation and strand concentrations.[17–21] Re-equilibration involves competition for unpaired strands, the common source of reactants used in the two competing assembly processes. At low Na^+ or K^+ concentrations (<240 mM Na^+ or <65 mM K^+), the antiparallel quadruplex formed by annealing *two* hairpin side-by-side forms. At higher salt concentrations, the parallel *four*-stranded quadruplex forms. As the DNA concentration is increased, less K^+ is required to induce the parallel-stranded quadruplex, which is preferred over the two-stranded antiparallel structure.

WC duplex formation is usually preferred relative to quadruplex formation because the duplex association rate is typically much faster than that for quadruplexes, but not always. For example, at elevated strand and K^+ concentrations, [d(CGC G_3 GCG)$_4$] quadruplex formation becomes preferred over the WC hairpin.[20] Quadruplex assembly competes successfully with the hairpin formation pathway for strands.

When sufficient monovalent cation is present, divalent cations typically stabilize duplexes, triplexes and quadruplexes. Concentrated nucleic acid/divalent cation solutions are prone to forming aggregates containing large strand stoichiometries.[61] Curiously, >20 mM Cd^{2+} or Zn^{2+} can dissociate examples of all three types of complex.[62] For example, the quadruplex [d(CGC G_4 GCG)$_4$] is dissociated with the following predispositions: $Cd^{2+} > Zn^{2+} > Ca^{2+} > Mg^{2+}$. Much higher concentrations of some divalent cations (Cd^{2+}, Zn^{2+}) are also known to dissociate duplexes and triplexes. The sensitivity

of duplexes, triplexes and quadruplexes to dissociate at comparatively low divalent cation concentrations may support significant transformation events among different forms of condensed nucleic acids in genomic chromatin, packaged virus particles or other niches.

A duplex DNA fragment in supercoiled plasmid DNA was found to form two different types of H-DNA triplex, with and without added Mg^{2+}. A triplex stabilized by G•G•C base triplet forms when the sequences shown in Figure 8(a) and (b) contains 2 mM Mg^{2+}.[10] In contrast, an alternative $C_H{}^+$•G•C-containing H-DNA triplex structure forms in the absence of Mg^{2+}.

B-form duplex DNA has between 15 and 20 surface-bound H_2O molecules per nucleotide.[63] In one structure, about 17 waters bind, five in the vicinity of each base pair, four associated with each phosphate and two bound to the sugar. All of the base pairs are associated with the same number of water molecules, water binding is approximately sequence independent. A spine of hydration can form in the minor groove of the crystal structures of AATT sequence-containing DNAs, reinforcing the B-form structure by participating in bidentate interactions with T O2 and A N3.[1,63] Energy studies suggest that these hydration interactions help stabilize the duplex. Osmotic pressure is a key energetic consideration; added osmolytes can dramatically affect the stabilities.

Certain repeating oligo(A•T) tract sequences can be placed in the proper position and appropriate phase with respect to the helix pitch, the length of one turn of the helix, to produce bent DNA.[64] Only properly phased sequences work because they ensure that subcontributions to the bend accumulate far enough to produce the fully realized change in net helix orientation. When the sequences are not properly phased, long-range bending does not occur.

This is a relatively extreme example of DNA structural microheterogeneity. Crystallography results demonstrated that there are sequence-specific differences in rotation between base pairs in B-form DNAs, lateral positioning of base pairs relative to the helix axis and propeller twisting of the two bases within a base pair with respect to each other, etc. (Figure 17a and b).[1,6,42] These specificities have been incorporated into rules that can be used to predict how sequence changes affect helical microstructures.

6.2 Ligand-induced Structural Transformations

Nucleic acids often undergo structural transformations when proteins bind. A vast canon of enzyme-catalyzed, sequence-specific covalent cleavages, modifications, ATP-requiring locomotion events, decoding and rearrangement reactions, etc., form the basis of modern molecular biology.[2,3,55] Protein structures must often adapt and mold to their ligand upon binding to accomplish these processes. Because the backbone of DNA is negatively charged, DNA-binding domains in proteins are typically composed of positively charged, often protonated, amino acids, arginine, lysine and histidine. Since the bases are prone to stacking interactions, the aromatic amino acids phenylalanine, tyrosine and tryptophan are also common in nucleic acid binding proteins. They function by stacking between base residues to form intercalative interaction in the [protein•DNA (or RNA)] co-complex.

The protonated, polycationic polyamines spermine and spermidine resemble the electropositive amino acids, providing a small molecular model to help understand how analogous protein fragments bind, neutralize and stabilize DNA and RNA structures in vivo. Spermidine is required to crystallize tRNAs and in many nucleic acid and [nucleic acid•protein] co-complex crystallization protocols.[1] It is thought to function by neutralizing the polyanionic tRNAs and reducing intermolecular repulsions in the crystal. Both of these polyamines induce the B- to Z-DNA transition, at micromolar concentrations when m^5Cs are present – almost three orders of magnitude less than the Mg^{2+} concentration required to do the same.

Specific DNA-binding elements in proteins mediate most known genetic control mechanisms. Two important duplex DNA-binding motifs, the helix–turn–helix and zinc finger, are very common in the DNA-interaction domains of repressor and transcription factor proteins.[55] Sequence-dependent differences in functional groups in the major and minor DNA grooves produce specific recognition sites, leading to protein-mediated recognition, specificity and regulation. Two DNA-binding proteins, e.g. transcription factors, often bind each other via two entwined α-helices, one contributed by each protein, called a leucine zipper.

Protein binding is usually fairly specific for one base sequence, the consensus sequence. In some cases, however, a broad range of sequences is recognized. An extreme example of broad RNA recognition specificity occurs with phage T4 late transcript regA mRNAs, which display a broad range of viable consensus binding sequences.[65,66] This range was studied quantitatively by assessing the propensities of randomized RNAs to evolve through a series of regA protein-binding selection steps using a technique called systematic evolution of ligands by exponential enhancement (SELEX). This process involves a series of consecutive cycles of substeps: nitrocellulose filter binding, reverse transcription, cloning to complete each cycle and sequence determinations following each round to follow the process. Tetraloop structures formed by the RNA strongly inhibit their

reverse transcription, being so stable they essentially stop protein transit.

A general model has been developed to understand specificity in protein–DNA binding interactions.[67] The researchers wanted to determine how repressor proteins specifically recognize their correct operator DNA and reject nonspecific DNAs. The findings highlight the subtlety of specific DNA recognition. Electropositive binding proteins all have an intrinsic propensity to bind any nucleic acid sequence by virtue of its polyanionic charge, the predominant externally recognizable property. The protein cannot bind too tightly or repression cannot be easily reversed; binding constants for repressor binding to specific DNAs are typically only about five-fold larger for the correct consensus sequence than for any sequence. All sequences are bound with comparable association rate constants (k_a). Specificity is maintained by having incorrect sites dissociate much more readily (quickly) than correct sites, i.e. the dissociation rate constant (k_d) is larger for correct than for incorrect sites. As a result, proteins stick to correct sites and are lost from incorrect sites. The high k_a ensures that the protein will rebind elsewhere, eventually sticking when the correct sequence is encountered.

Modular components, excised from their full molecular context for study, are being used to learn how they function in their more complicated niche. A few selected examples are described briefly below. In each of these cases, the nucleic acid structure interacts with a protein ligand that contributes significantly to the net energetics of the process.

The arginine fork motif mediates specificity in the HIV [tat protein•TAR RNA] binding interaction.[68] In this model, an internal bulge and a nearby six-nucleotide loop mediate specific binding of the tat protein, leading to transcriptional activation. Upon arginine binding, the bulge changes conformation, and essential nucleotides for binding form a U•A•U base–triple interaction that stabilizes arginine hydrogen bonding to a nearby G and phosphates.

The HIV Rev peptide binds stem–loop IIB of the Rev Response Element RNA. The Rev peptide has an α-helical segment that binds in the major groove of the RNA near a purine-rich internal loop, with several arginines making base-specific contacts, including a G•A base pair. NMR studies demonstrated that the phosphodiester backbone adjacent to a G•G base pair adopts an unusual structure that allows the peptide to access a widened major groove.[69] The major groove of A-RNA is normally deep and too narrow to accommodate an α-helix, thus requiring non-WC interactions to widen the groove.

The protein CBP2 binds RNA tertiary structure and is required for efficient splicing of a yeast mitochondrial Group I intron. CBP2 must wait for folding of the two RNA domains that make up the catalytic core before it can bind.[70] Subsequently, association of the 5′ domain of the RNA is stabilized by additional interactions with the protein. Thus, CBP2 functions primarily to capture otherwise transient RNA tertiary structures.

ACKNOWLEDGMENT

We thank Rebekah Gunn for obtaining copyright releases and Professor Dennis Brown for providing support. C.C.H. thanks his students, professional colleagues and mentors, Professors Jack Horowitz, Ignacio Tinoco, Jr and Paul Agris, for their contributions, insights and enthusiasm for this ''good fight''.

ABBREVIATIONS AND ACRONYMS

A	Adenine
br^{5}C	5-Bromocytidine
br^{8}G	8-Bromoguanosine
C	Cytosine
CD	Circular Dichroism
DSC	Differential Scanning Calorimetry
G	Guanine
HIV	Human Immunodeficiency Virus
IR	Infrared
m^{5}C	5-Methylcytosine
mRNA	Messenger RNA
NMR	Nuclear Magnetic Resonance
NOE	Nuclear Overhauser Effect
SELEX	Systematic Evolution of Ligands by Exponential Enhancement
snoRNA	Small Nucleolar RNA
T	Thymine
tRNA	Transfer RNA
tRNA^{Phe}	Phenylalanyl Transfer RNA
U	Uracil
UV	Ultraviolet
WC	Watson–Crick

FURTHER READING

We have attempted to present an even-handed view of this vast field, but this account is limited. We included the following Further Reading to broaden the scope, yet minimize space. We have glossed over many important theoretical developments, biotechnological advances and medical applications of nucleic acids. Consult the cited articles for much more about the inner workings and uses of these fascinating molecules.

Our sentiments about nucleic acids track well with those of author Jim DeRogatis: ''Like any history, this one is subjective. Another account of psychedelic rock [Jim's subject] could be written emphasizing an entirely different set of artists (scientists in our case), and I would enjoy reading it. . . . My goal was to share my enthusiasm for music (nucleic acids studies) that I consider to be some of the finest that rock (biophysical chemistry) has produced''. [J. DeRogatis, *Kaleidoscope Eyes*, Citadel Press, Secaucus, NJ, 1996.]

Optical mapping is a system for the construction of ordered restriction maps from single deoxyribonucleic acid (DNA) molecules. DNA molecules bound to derivatized glass surfaces are cleaved with restriction enzymes and imaged by fluorescence microscopy. Cut sites are visualized as gaps between cleaved DNA fragments, which retain their original order. Optical mapping offers advantages over electrophoretic methods of restriction enzyme analysis, which require separate techniques for separating cleaved DNA fragments and determining fragment order. Furthermore, small amounts of DNA are required for optical mapping analysis. By determining the existence of these sequence-specific cut sites and the distances between them, a precise landmark map of the DNA sequence can be constructed. Prokaryote and eukaryote DNA can be mapped. Maps can be constructed from both cloned DNA and genomic DNA. Restriction maps can be constructed for whole genomes by overlapping maps derived from individual molecules. Such maps provide a useful scaffold for accurate alignment of sequence contigs generated by a shotgun sequencing approach and a means of comparing populations and strains.

1 INTRODUCTION

1.1 Principle

Optical mapping is a single molecule approach for the rapid construction of ordered restriction maps.[1] It dispenses with electrophoretic approaches and uses fluorescence microscopy directly to image individual DNA molecules bound to specially derivatized glass surfaces which have been cleaved by restriction enzymes. Restriction enzymes are enzymes that recognize and then cleave DNA at a sequence specific site, usually a four, six or eight nucleotide motif. Different restriction enzymes recognize different motifs. A restriction map is a linear array of sites on DNA cleaved by one or more restriction enzymes showing the mass, in basepairs (bp), of the ordered fragments predicted from the digest.

Large DNA molecules, greater than 10 kilobases (kb) in size, are mounted on silanized glass surfaces. Fluid flows elongate the DNA molecules and electrostatic interactions hold the stretched DNA molecules on

the surface. Molecules are digested with a restriction enzyme. Cleavage sites are visible as small gaps between DNA fragments, which retain their original order. DNA is stained with an intercalating dye, visualized by fluorescence microscopy and digital images are recorded. Fragments are sized by measuring integrated fluorescence intensity and ordered restriction maps of single molecules are constructed. A restriction map created from a single DNA molecule is limited in its accuracy by the resolution of the microscope, the imaging system, surface conditions and the biochemistries used. Statistical approaches are therefore used to construct finished maps from an ensemble of imperfect maps such as those derived from partially digested molecules. Consensus maps of cloned DNA are created using a Bayesian inference scheme.[2] Maps of genomic DNA are contiged using Gentig software.[3] The final maps are an average of many individual maps.

1.2 History

Optical mapping was first reported in 1992. In the original method, ensembles of yeast chromosomes fluorescently labeled with 4,6-diamidino-2 phenylindole dihydrochloride (DAPI) were elongated in a flow of molten agarose generated between a coverslip and a microscope slide.[4,5] The DNA was fixed in an elongated state when the agarose gelled. Restriction enzymes were present in the molten agarose and the DNA was cut when magnesium ions diffused into the gel. As the DNA relaxed, the cut sites in individual molecules were resolved by imaging the receding cut ends by time-lapse video microscopy. Ordered restriction maps were constructed by measuring the relative fluorescence intensity and apparent molecular contour length of a number of DNA fragments, followed by averaging. Fragment sizes determined by optical mapping correlated with sizes obtained by pulsed field gel electrophoresis (PFGE)[6,7] and were more informative since the fragment order was determined concurrently. The approach had other advantages over PFGE in that problems associated with disambiguation of co-migrating bands on pulsed field gels were obviated.

In an advanced approach, DNA was digested on open glass surfaces which had been coated with polylysine.[8] DNA was bound to the surface by electrostatic interaction. The interaction was strong enough to retain cut fragments on the surface but weak enough to allow cut ends to relax to form visible gaps. Since restriction enzyme activity can be inhibited by some DNA binding fluorochromes,[9] DNA fragments were stained with ethidium homodimer fluorochrome following digestion. DNA fragments were imaged with a charge-coupled device (CCD) camera and fragments as small as 800 bp[8] could be imaged and sized, representing a major improvement from the original agarose gel-based optical mapping approach which had a limit of resolution of 60 kb.[5] The current approach uses open silanized glass surfaces which reliably retain small fragments in the 1–10 kb range.[10,11]

The approach has been developed in a number of other areas and can now be used to map a wide variety of clone types including λ-bacteriophage,[8] bacterial artificial chromosomes (BACs),[10] yeast artificial chromosomes (YACs)[12] as well as genomic DNA from prokaryotes[13] and eukaryotes.[14] The range of effective restriction enzymes has increased,[10] image acquisition has accelerated and data analysis has been refined.[2,11] Samples can now be gridded onto the surface enabling parallel processing.[11] These developments have increased throughput and provide the foundation for automated approaches to mapping DNA.

1.3 Optical Mapping of Cloned DNA

Mapping of cloned DNA offers advantages in that multiple copies of the same sequence are present on the same surface (Figure 1). Statistical approaches are used to construct finished maps from an ensemble of imperfect maps derived from individual molecules. Imperfect maps are generated as a consequence of partial digestion, desorbtion of small fragments, inaccurate sizing, etc. The final optical map is averaged from 20–40 single molecule maps.[10] BAC maps can be contiged together by aligning restriction sites to cover large genomic regions and generate minimal tiling paths.[10]

Figure 1 Digital fluorescence micrograph of some typical BAC molecules. This 100 kb BAC, derived from the human Y chromosome, was digested with *Nhe*I.[15] Ordered restriction fragment sizes are 26.6, 3.5, 2.9, 29.1, 3.1, 2.3, 12.4, 6.2, 4.5, 5.7 and 3.5 kb.

Figure 2 Digital fluorescence micrograph of a typical genomic DNA molecule. A *Plasmodium falciparum* molecule digested with *Nhe*I is shown with its corresponding optical map. Comparison with the consensus optical map shows this molecule to be an intact chromosome. Image composed by tiling a series of 63× (objective power) images using ''gencol''. Co-mounted λ-bacteriophage DNA is used as a sizing standard and to estimate cutting efficiencies.

1.4 Optical Mapping of Genomic DNA

Optical mapping of genomic DNA enables restriction maps of entire microbial genomes to be constructed.[13,14] The substrate is large randomly sheared genomic DNA molecules 0.4–3.0 Mb (megabases) in size (Figure 2). The resulting maps generated using such a ''shotgun optical mapping'' strategy have many overlapping restriction sites permitting contig formation either by visual alignment[14] or by ''Gentig'' software (described below).[3,13] Library construction is obviated enabling mapping of organisms with AT-rich DNA, which is difficult to clone. Also, cloning artifacts are precluded, enabling more accurate maps to be generated. Such maps have proved invaluable as a scaffold for assembling of sequence contigs and as a means of sequence verification.[16] Optical mapping also provides insight into the genomic structure of the organism, revealing the presence of large extrachromosomal elements, which can only be identified at the single molecule level.[13]

2 METHODOLOGY

2.1 Cleaning of Glass Surfaces

Optical mapping surfaces must be cleaned thoroughly before use to ensure uniform derivatization and optical transparency. For safety and cleanliness a self-contained acid boiling system, built from pyrex glass and Teflon™ tubing and assembled in a fume hood, works best. No vacuum grease is used to seal the joints. A sodium hydroxide scrubbing system neutralizes acid vapors. Coverslips are racked in custom-made Teflon™ racks, which hold the coverslips snugly on three edges, and cleaned by boiling in concentrated nitric acid (HNO_3) for 24 h. The system is rinsed extensively with deionized dust-free water until the effluent attains pH 6. The cleaning procedure is repeated with concentrated hydrochloric acid (HCl) which hydrolyzes the glass surface, preparing it for subsequent derivatization. The racked coverslips are rinsed extensively and then sonicated in deionized water to remove residual acid which collects between the Teflon™ parts in the racks. Residual water is then removed by sonicating the racks in distilled ethanol. The cleaned coverslips are stored at room temperature in the racks under distilled ethanol in polypropylene containers.

2.2 Derivatization of Glass Surfaces

Cleaned coverslips are derivatized in slotted Teflon™ racks which hold the coverslips by one edge. Surfaces are derivatized for 48 h at room temperature on a rotary shaker in 3-aminopropyltriethoxysilane (APTES), between 7 and 28 μM, in ethanol.[10,12,17] Macroscopic derivatization parameters such as silane concentration and duration of silane treatment alter the surface charge density which plays a critical role in surface-based optical mapping. The surfaces are checked for optimal performance by estimating the hydrophobicity by measuring the contact angle and assaying the degree of DNA stretching and fragment retention. Derivatized surfaces can be stored in treatment solution for a few weeks. Surfaces can also be derivatized with 3-aminopropyldiethoxymethylsilane (APDEMS)[14] or 3-(triethoxysilylpropyl)trimethylammonium chloride (TESP).[11]

2.3 Preparation of DNA Molecules

Circular BAC and cosmid molecules are prepared by standard alkaline lysis protocols[18] or commercial plasmid preparation columns. Molecules are linearized with λ-terminase prior to surface mounting.[10] λ-Terminase is an endonuclease which cleaves at the λ *cos* site. Occasionally, circular DNA is linearized by restriction digest utilizing a *Not* I site in the polylinker of the cloning vector when no internal *Not* I sites are present in the insert.[10]

Increasing the size of measurable genomic DNA molecules decreases the number required for mapping a complete genome.[19] To minimize shearing, approaches similar to those used to prepare large DNA molecules for PFGE are used.[6,7] Genomic DNA is isolated from cells embedded in low melting point agarose gel inserts which are treated with proteinase K and detergents. Essentially intact DNA is isolated following melting of

the agarose. Physical manipulations such as pipetting can shear large DNA molecules so these are kept to a minimum, and where necessary, wide bore pipetting devices with a slow delivery rate are used. Molecules over 2 Mb can be mounted.[13] Shearing of genomic DNA can also be minimized by condensation of DNA molecules with spermine, a polyamine which collapses DNA coils embedded within agarose.[12] The subsequently molten agarose can be subjected to manipulations as severe as vortexing which would ordinarily shear DNA. The DNA particles are decondensed by washing of gel inserts in spermine-free buffer supplemented with NaCl.

2.4 Mounting of DNA Molecules on Surfaces

DNA molecules exhibit rod-like behavior below ~3 kb, and show evidence of random coil behavior above 3 kb.[20] DNA molecules interact with derivatized surfaces via electrostatic interactions between the anionic DNA and cationic surface. Molecules attach to the surface at one end and then stretch out in the fluid flow.[11,21] Efficient binding and analysis of molecules relies on a balance between flow and electrostatic forces. High-fluid flow combined with a high surface charge density causes overstretching of the molecules, leading to breakage of molecules during and after mounting. Low-fluid flow combined with a high-surface charge density causes understretching of the molecules, leading to coils of DNA deposited on the surface.

By carefully controlling surface conditions, large DNA molecules can be mounted without significant breakage.[10,12] Too high a surface charge density yields poorly stretched, or stretched intact DNA molecules which fail to digest.[8,12] This may be due to occlusion of enzyme binding sites caused by severe adsorption of the molecule to the surface. Alternatively, cleavage may occur, but insufficient relaxation occurs to produce an observable gap.[22] Indeed, both mechanisms may apply. Insufficient charge density leads to desorbtion of DNA fragments smaller than about 1 kb from the charged surface following digestion. The larger the DNA molecules, the lower the required surface charge density. Genomic DNA requires lower charge density than BACs, which require lower charge density than cosmids.[17] Molecules mounted by the peeling method require lower surface charge density than those mounted by the spotting method (see below). Because optical mapping uses fluorescence intensity measurements for mass determination, complete elongation of the DNA molecules is not required for mapping, but it does facilitate the data analysis and provides more mapping information because more cutting sites are resolved.[17,23] DNA is mounted by either ''peeling'' or ''spotting'' protocols.

In the peeling protocol, a few microliters of DNA solution are pipetted onto a microscope slide and a derivatized coverslip is carefully placed on top of the sample to spread out the drop. The coverslip is removed carefully with forceps (''peeled'') and rinsed in Tris–ethylenediaminetetraacetic acid (TE) buffer.[17] The amount of DNA mounted on a surface is titrated on a surface-by-surface basis to give optimum numbers of DNA molecules per microscope field of view. A high density of mounted molecules gives more information but also leads to crossed molecules and an inability to resolve groups of fragments from different molecules. DNA molecules have also been mounted by motor-driven movement of a meniscus held at a 45° angle between a coverslip and a derivatized slide.[24] A procedure for binding DNA molecules at a gel/solution interface has also been developed.[25]

Gridding of multiple samples on a single surface and processing them in parallel is a strategy employed in hybridization-based approaches[26–29] and also in optical mapping.[11] The spotting protocol permits multiple DNA samples to be mounted on a single surface. This enables

Figure 3 Digital fluorescence micrographs of gridded spots containing fluid fixed molecules. Droplets of λ-bacteriophage DNA onto APTES treated glass surfaces, dried and stained. (A) Section of a 10 × 10 spot grid on a derivatized surface. Image composed by tiling a series of 16× (objective power) images. (B) Close-up of a DNA spot within the grid. Image composed by tiling a series of 16× images. (C) Magnified image of elongated DNA molecules contained within the spot shown in (B) before restriction digestion, 100×. (D) DNA molecules in (B), different field, after digestion with *Bam*HI (100×). Bars: 20 μm (A, B); 5 μm (C, D).[11] (Reprinted from Jing et al., *Proc. Natl. Acad. Sci. USA*, **95**, 8046–8051 with permission. Copyright (1998) National Academy of Sciences, USA.)

digestion and analysis in parallel. Droplets of DNA samples are "spotted" in 10×10 grids using a modified commercially available Biomek laboratory automation robot (Figure 3). The fluid flows generated within drying droplets bring the DNA molecules closer to the surface where they bind in an elongated conformation. The robot is able to deposit one sample approximately every 10 s. Spotting tools include glass capillaries, pipette tips or solid tips which deposit volumes of 10–20 nL using several programs which alter spotting patterns. Such automated high-density deposition techniques make optical mapping an ideal high throughput system for genomic analysis of clones.

2.5 Restriction Digestion of DNA Molecules on Surfaces

The optimal restriction enzyme digestion conditions, in terms of digestion time and enzyme concentration, depend on the enzyme being used and the surface characteristics. Cutting efficiencies are routinely greater than 80%. Efficient cutting of genomic DNA is obligatory for confident contig formation by Gentig software (described below). Typically, 5–20 units of enzyme in 50–200 μL of buffer, are pipetted onto the surface. Digestion is carried out at room temperature for 10 min to 2 h in a humidified closed chamber. The digestion reaction is terminated by aspirating off the enzyme solution and washing the coverslip twice with TE buffer and then distilled water. DNA molecules are stained with oxazole yellow homodimer (YOYO-1) in 20% β-mercaptoethanol. YOYO-1 is a fluorescent dye which bis-intercalates between the DNA bases at one molecule (two fluorophores) per four bps.[30] YOYO-1 solution is pipetted onto a microscope slide and the sample coverslip is placed on top of it. The edges of the coverslip are sealed onto the slide with transparent nail polish. Alternatively the coverslip is covered with 100–200 μL YOYO-1 solution and rinsed with distilled water after 1 min to decrease background staining.[17]

2.6 Choice of Restriction Enzyme

Four, six, and eight bp cutter enzymes can digest surface-mounted DNA. The more frequently a restriction enzyme cuts, the smaller the fragments will be and the higher the resolution of the optical map. However, a compromise must be made since enzymes that cut too frequently generate a population of small fragments which desorb from the surface, generating less accurate maps.

The choice of restriction enzyme also depends on the GC/AT content of the sample DNA, which can vary greatly depending on the organism and the recognition sequence of the enzyme. The GC/AT content will determine the average fragment size for a given enzyme. Human DNA is roughly 50% GC but the content of microorganisms varies greatly. For example, *Plasmodium falciparum* DNA is only 18% GC. *Nhe*I and *Bam*HI were chosen to map this organism since they recognize sequences with a GC bias (GCTAGC and GGATCC) and would prevent too frequent cutting. Assuming a random distribution of nucleotides across the genome, the predicted cutting frequency with these enzymes would be every 91 kb. The average sizes of the fragments generated by optical mapping of the whole genome were 24 kb and 32 kb, respectively.[14] *Deinococcus radiodurans* DNA is 68% GC, predicting an *Nhe*I cutting frequency of 3 kb. When this organism was mapped with *Nhe*I, the average size of the fragments was 29 kb.[13] This demonstrates that the GC/AT content of these organisms is not randomly distributed and each genome must be evaluated empirically on a organism by organism basis. Consequently, before optical mapping begins, a digest is performed in solution with a variety of candidate enzymes and a distribution of fragment sizes is determined by PFGE.

Enzymes that work in a NaCl-containing buffer (50–150 mM) are required since salt-free buffer does not permit relaxation of the DNA on the surface following digestion. Higher salt concentrations cause more DNA relaxation and less retention of small fragments. The restriction enzyme buffer needs to be compatible with the surface charge density. Surfaces with high charge density are used with high salt buffers and surfaces with low charge density are used with low salt buffers. Buffers containing potassium salts in place of NaCl alter the integrity of the surface-mounted DNA, in a presently unknown manner, and therefore enzymes that work in these buffers cannot be used. Consequently, not all restriction enzymes can be used for optical mapping.

2.7 Sizing of DNA Molecules

Fluorescence intensity measurements are used for DNA fragment mass determination. An internal standard of known length is used to size fragments accurately. In the case of cloned DNA this can be the vector which has *Not*I restriction sites in the polylinker at either end.[10] The pBAC108L vector, for example, gives a 6.9-kb sizing standard. Circular molecules can therefore be mounted on surfaces and sized in a circular form. In the case of genomic DNA, λ-bacteriophage DNA (48.5 kb) or cosmid DNA (about 45 kb) can be co-mounted with the sample (Figure 2). Cutting efficiency can also be estimated if the co-mounted standard possesses a restriction site for the enzyme used for mapping.

2.8 Instrumentation

The optical mapping workstation (Figure 4) is built around a Zeiss™ 135 Axiovert inverted microscope

Figure 4 Optical mapping workstation. The schematic illustration shows how the microscope, silicon intensified target (SIT) video camera, cooled CCD camera, LUDL™ controller and Sun workstation are integrated.

equipped for epifluorescence, with several different objectives (40, 63 and 100× Zeiss™ plan-neofluor oil immersion) allowing for imaging of biomolecules of a wide range of sizes. The 100× objective is most commonly used, whereas the 63× objective is used for clones larger than 200 kb. Filter packs allow for imaging of biomolecules labeled with fluorescent dyes of different spectral properties. The microscope is equipped with a Dage™SIT 68GL low light-level video camera and accompanying monitor for automatic and manual focusing, and a Princeton Instruments cooled CCD camera (1317 × 1035 pixels, KAF 1400 chip, 12-bit digitization) for acquiring high-resolution digital images. Automatic features such as movement of the microscope stage (0.1-μm resolution), image collection, light shutter operation and video autofocusing are controlled by a LUDL™ Electronics box, which contains a LUDL™ Electronics MAC 2000 interface bus, housing all interface cards (PSSYST 200, MCMSE 500, MDMSP 503, AFCMS 801, FWSC 800, and RS232INT 400). The LUDL™ MAC 2000 is interfaced via a RS232 serial connection to a Sun Microsystems™ SPARC 20 dual processor computer workstation. The CCD camera is also interfaced, via a pentium-based microcomputer controller and a distributed network, to the Sun workstation. The Sun workstation is part of a distributed network on which interactive and automatic image processing is performed. Software for control of the above peripherals is written in the C programming language. The optical mapping workstation is mounted on a floating optical table.

2.9 Microscope Automation Software and Collection of Images

DNA molecules are imaged using optical map maker (OMM) software, operated through a collection of user-friendly interfaces, and the image collection process can be followed on the Sun workstation monitor.

OMM software includes full computer control of all the workstation functions such as focusing, sample translation (x–y position), switching between SIT and CCD cameras, and image collection. Manual and fully automatic modes are incorporated. Image acquisition parameters such as imaging time, sample grid position and size, and spot diameter can also be varied. A sample image is collected by the CCD camera and the final imaging time is then set by the operator so that the pixel value on any part of the molecules is below saturation (4095 gray levels). Digital images can be acquired by the workstation at the rate of 4 min^{-1} (using 5 s imaging time). The development and implementation of automated microscope operations has enabled operator-free imaging of optical mapping surfaces. An operator can enter the coordinates of a series of gridded spots and images are subsequently collected and tiled together automatically, only from the areas on the surface where DNA has been spotted.[11] As part of a developmental path for large clone mapping with automatic image collection, the program ''Mark and Collect'' has been developed. This software saves the operators time spent waiting for images to be collected and transferred to the file system, which normally takes about 10 s per image. Microscope fields of interest are selected by the operator and the coordinates stored. When enough areas of the optical mapping surface have been identified the program subsequently moves the stage and collects the images. The image acquisition output is linked to the automatic map-making routines, so that after the images have been acquired and stored on hard disk arrays they can be either directly submitted for automatic image processing and extraction of restriction map data or saved for later processing. The OMM system can run on a network of other workstations. Access to all aspects of the OMM data and processing is made through one shared directory hierarchy. This file system structure and the accompanying software libraries provide uniform controlled access to all collection and processing activities and data. Several specially designed ''viewers'' permit the user to follow the different steps of the image analysis visually, so that convenient assessment and troubleshooting can be performed. A distributed processing system allows all the available computational resources on the network to be shared.[17]

2.10 Correction of Images

The CCD camera produces images composed of 1317 × 1035 pixels of 12 bits each which are read out and stored as an array of unsigned 16-bit values. The intensity value for a pixel at no light is the dark value, and an image taken with the microscope shutter closed is a dark image. This dark image, which represents the electronic noise in the CCD chip, varies from camera to camera and with the parameters used for taking the image (exposure time, etc.). The first correction made to an optical mapping image is to subtract the corresponding dark image. The second correction, flatfield correction, is carried out to adjust for differences in the amount of light registered by a particular pixel that are not due to the difference in distribution of dye in the sample. Such variations can be due to nonuniformity of the light source, differences in the light path (smudges on optical components, etc.), and possibly other factors in the CCD and readout electronics. The correction involves dividing each pixel value in the image by the corresponding pixel value in a bright image, an image of a thin, in-focus, and uniformly fluorescent sample. Since the only fluorescence of interest is that emanating from dye bound to DNA molecules, other sources of fluorescence are considered background and the subtraction of this background contribution is the last correction made. Based on the assumption that the major source of background is unbound dye on the surface and that this does not vary rapidly, the background value for each pixel can be estimated. First, the median pixel values for pixels on concentric circles around the pixel in question are found. Then, a median of medians is taken, a median image calculated and a Gaussian smoothing operation applied to give the final background image. This image is subtracted from the flatfield corrected image.[17]

2.11 Analysis of Images

The purpose of the analysis of optical mapping images is to find the cognate fragments derived from a single DNA molecule, and for each fragment calculate a signal representing the intensity in the image along the length of the molecule. DNA molecules are found by looking for long thin bright objects which have a dominant direction.

In the first phase, an algorithm identifies these isolated regions in the image, using both the fluorescence intensity and local directionality properties at each pixel, where each region contains the fragments of a parental molecule not overlapping with other molecules. This is done by first applying a ridge filter[31] to the input corrected image which produces 16 new images. Each image corresponds to one of 16 different directions and the value of a pixel in one of these images represents a calculation of the degree to which the pixel appears to lie on a ridge in the particular direction. An image is then constructed which contains, at each pixel, the highest of the 16 values for that pixel. A threshold value is picked so that the peak on the histogram for an area containing the segment to be measured is the midpoint between the threshold value and the lowest background value. A threshold is calculated for the new image and objects are identified as contiguous collections of pixels whose values exceed the threshold. At this point the objects (collections of pixels

with high numerical values) consist of pixels which are on ridges in some of the 16 directions, but since all 16 directions are included, and since the ridge filter tends to swell up in regions which have no predominant direction (e.g. at the ends of molecules), this image has a tendency to merge molecules which happen to be close to each other. To separate these molecules, the ridge filtering process is repeated for nine, then five, and finally three directions so that, in the final image, the objects consist of pixels lying along a ridge in one of three directions. This process has been shown to find and separate DNA molecules.

In the second phase, a path down the center of the molecule (the ''backbone'') is computed using Dijkstra's ''all paths least cost'' algorithm.[32,33] A pixel in the middle of the molecule is chosen and the algorithm is applied to find the lowest cost path (traversing the molecule one step at a time from a pixel to one of its eight neighboring pixels) from the first pixel to each other pixel in the object. The cost of a path is the sum of the costs of the individual steps from pixel to pixel, and the cost function applied to each step favors moving to a pixel which is bright enough to be in the center of the molecule, but does not favor brighter pixels so strongly that the path wanders all over the middle of the molecule looking for the very brightest pixels despite the extra length. The paths from the first pixel to all boundary pixels are evaluated to identify an end-point pixel and the process is repeated using the end-point pixel instead of the first pixel. This finds the other end-point pixel and the path to it is the backbone. A smooth intensity signal along the backbone is then computed; for each position along the backbone, the intensity is calculated by summing the intensities for a set of pixels which are close to the backbone and lying along a line orthogonal to the backbone at that position. This intensity signal is then used to determine potential cut sites and estimated masses of all the potential fragments in that molecule. The estimated fragment mass data is normalized, and then, together with the information about the order of the fragments, collected for statistical analysis by the map-making program.

Images of single digested DNA molecules are taken using ''GenCol'', a semiautomatic image collection software which allows storage and seamless tiling of consecutive CCD images, covering the entire length of long genomic DNA molecules which span multiple microscope fields and is necessary for imaging of extraordinarily long DNA molecules.

The program ''visionade'' is an interactive graphical editing tool that allows a user to process a group of optical mapping images quickly, identifying fragments and molecules in the images with a few point-and-click actions. In the optical mapping system this step is done after a group of images has been collected and automatically flattened. Visionade is run on a group of images that contain molecules that are processed together to create a restriction map; e.g. a set of overlapping images containing a long genomic molecule and many copies of a smaller standard molecule which are used to size the fragments of the genomic molecule (see below). The user brings up an image, adjusts the color mapping to make the fragments clear, uses a threshold slider in the interface to color the fragments, clicks on the fragments to identify and number them, and then clicks again to group the current set of fragments into a molecule. The outputs of visionade are mask images locating the fragments and molecules. These outputs are combined with the flattened images to measure the sizes of the fragments in the molecules and this data is the input to the statistical analysis program ''lcluster'' (see below) which is a novel computational approach to map construction from optical data and finds the consensus map.

2.12 Map Construction Using Cloned DNA

The map making program ''lcluster'' gathers all of the per-molecule computations from all images and operates on them together. Here, the complete restriction map is computed by testing a set of plausible hypotheses about the restriction cleavage sites and choosing the most likely hypothesis supporting the previously accumulated data. The program starts by filtering out unsuitable molecules based on several criteria. (1) A molecule must have a total length in pixels between a specified minimum and maximum. (2) A molecule must not be within 10 pixels of the image boundary. (3) The maximum angle of curvature over the entire length must be below a specified angle (usually 30°). (4) The total intensity of the molecule due to pixels outside a specified distance from the backbone must be less than a specified threshold. These criteria tend to exclude most partial and overlapping molecules. Bayesian inference techniques enable the construction of maps from noisy data. For example, the map construction algorithms can produce maps from a population of partially digested clone molecules having a digestion rate as low as 15%.[2] Bayesian estimation is used to determine the optimum way of accounting for each of the fragments in the filtered data set. A hypothetical model of the map is formulated, which specifies the following parameters: cut locations, the variance of cut site measurements, the cutting efficiency and the sample purity. Suitable probability distributions are applied to each of the parameters in the model. The cut locations follow a Gaussian distribution, false cuts are assumed to be uniformly distributed over the length of the molecule, the number of false cuts follow a Poisson distribution, and the cutting frequency is a simple function of the number of cuts. The object of the analysis is to find the maximum-probability model of the map given the data. The program

considers about 8000 models for each model size, i.e. maps of 2, 3, 4... fragments, and picks the 32 best models of each size, whose parameters are then optimized locally to converge to the nearest maximum in probability space. The best model of any size is accepted as the solution map if its probability density is significantly better than that of any other model.

2.13 Map Construction Using Genomic DNA

Whole genome optical maps are constructed by mapping large randomly sheared genomic DNA molecules. Overlapping maps are contiged by aligning restriction sites. Map contigs can be laboriously assembled manually over a course of weeks,[14] or within minutes using ''Gentig'' software which automatically assembles map contigs and a consensus map from optical mapping data.[13] Gentig uses a greedy algorithm with limited backtrack to find an almost optimal scoring set of map contigs, while constraining the false positive error rate below a negligible value. This approach ensures that the computed contigs are largely correct, although it fails to minimize the number of contigs. On the other hand, Gentig avoids the high computational complexity that would be incurred in attempting to find the optimal placement, a problem shown to be computationally infeasible in the most general setting.[3] Molecular length and digestion efficiency control fragment alignment and are well-modeled by prior probabilistic (Bayesian) analysis.[3] The Bayesian approach requires careful choice of parameters and a known prior statistical distribution of error sources. The standard deviation, digestion rate, false cut rate and false match probability can be altered to change the number of molecules that Gentig contigs together. The consensus map computed by Gentig is free of errors due to partial digestion, sizing error and false cuts.

The scoring function is computed from a Bayesian probability density estimating the probability that the two distinct component maps could have been derived from the proposed placement while subject to various data errors. The data errors which are modeled include sizing errors, missing cut sites, and false ''optical'' cut sites. First the most likely placement is hypothesized, then the probability density is computed for the mismatch errors in the component maps given the hypothesized placement and the error model. The second step is similar to the Bayesian probability density computation;[2] one difference is that simplifying assumptions are made to improve computational efficiency. In particular, the hypothesized placement is computed by averaging of the contiged fragment sizes, rather than a true Bayesian probability density maximization with fragment sizes as parameters. Furthermore, good estimates of the error model parameters are assumed to be known a priori, but further improved by a re-estimation from the data using a limited number of iterations of a true Bayesian probability density maximization. The best offset and alignment between a pair of maps is finally computed by an efficient dynamic programming algorithm, thus avoiding a potentially exponential complexity.[15]

2.14 Visualization of Map Data

Whole genome maps composed of many restriction sites and deep contigs are viewed with ''ConVEx'' (Contig visualization and exploration tool), which is a multiscale zoomable interface for cognition of large high-resolution contiged restriction maps.[34] Users can examine the consensus maps together with the raw uncorrected data. Multiple representation of the graphical objects is presented in a scale-dependent manner and a powerful ''lens'' mechanism analyzes the underlying sequence data, enabling real time browsing of very large reference maps. The lens mechanism is augmented with a programming language (S-Lang language) allowing the user to create their own customized lenses. Such a lens (or a portfolio of lenses) provides a powerful tool for a user to examine the vast amount of data quickly stopping only infrequently to note a pattern, a point of interest or some editing of the data. Lenses facilitate examination of the global structure of the contig and provide annotation and editing mechanisms, allowing users to communicate interesting features such as STS (sequence tagged site) markers, even sequence reads.[15]

3 OPTICAL MAPPING TO CHARACTERIZE GENOMES

3.1 Optical Mapping for Sequence Assembly and Verification

A prerequisite for characterizing and sequencing complex genomes is the availability of high-resolution maps of cloned DNA molecules. Optical maps support whole genome sequencing in two ways. First, optical maps are used to generate minimal tiling paths of large insert clones.[10] Overlapping clones are contiged together by alignment of restriction sites (Figure 5). A minimal tiling path of clones is then chosen to minimize redundant sequencing. Second, optical maps of cloned or genomic DNA are extremely valuable to assist and ultimately confirm assembly of sequence generated by a shotgun approach (Figure 6).

A shotgun strategy has been employed to sequence the genomes of a number of microorganisms completely and sequencing of the human genome is an ongoing endeavor. DNA can only be sequenced in small portions

Figure 5 A BAC contig of human chromosome region 11p13. (a) images of individual clone molecules arranged in a contig. (Bar 5 μm) (b) *Bam*HI restriction maps of corresponding clones.[10] (Reprinted from Cai et al., *Proc. Natl. Acad. Sci. USA*, **95**, 3390–3395 with permission. Copyright (1998) National Academy of Sciences, USA.[10])

of about 500 bp. Shotgun sequencing essentially involves random fragmentation of the target DNA sequence, which can be an entire microbial genome or in the case of larger metazoan genomes a large insert clone such as a BAC. The resulting small fragments are cloned and sequenced. The assembly of sequence into contigs is accomplished using a number of software packages that read raw sequence from traces, search for homologous sequence to construct contigs, and allow significant editing of intermediate results. The entire target is redundantly sequenced to ensure maximal coverage and sequence accuracy. Nevertheless, some gaps still remain, often due to under representation in the library.

Optical maps can be used as a scaffold for accurate alignment of sequence contigs.[15] A restriction map is created for each sequence contig in silico and optimally aligned with the optical map. Optical maps can also characterize gaps in terms of breadth and location and may facilitate closure techniques such as long-range PCR.[35]

3.2 Very High-resolution Optical Mapping

The information content of a multiple restriction enzyme map is greater than the sum of its parts. Smaller sequence contigs can be placed on a multienzyme map. Multienzyme maps are generated by constructing single enzyme maps and then, by a series of double digestions, or use of available sequence information, these maps are combined into one dense construct. Optical maps of BACs digested with seven different enzymes have been overlaid to create a very high-resolution map with average fragment size 1.2 kb.[10] Although this gives a very high density of markers, this resolution is still insufficient to anchor single sequence reads or genes.

Optical maps of genomic DNA have been linked using available sequence information.[14] If a sequence contig contains restriction sites for two or more of the enzymes used to make the optical map, this contig can act as a linkage point to orient and align single enzyme optical maps. Rare cutter maps can be linked to existing frequent cutter maps by digesting the DNA into large fragments in a test tube with the rare cutter and then mounting these fragments on the optical mapping surface and mapping with the frequent cutter.[13] The resulting maps are contiged against a consensus map using just the frequent cutter. Blunt ended, abutting contigs indicate

Figure 6 Optical maps provide a scaffold for assembling sequence contigs. The analysis scheme shows alignment of sequence contigs with a consensus optical map generated by alignment of overlapping restriction fragments generated from genomic DNA molecules or large insert clones. Restriction maps are generated in silico from sequence data. Restriction sites on maps and sequence can be used to anchor sequence contigs. They can also characterize gaps in terms of breadth and location and may facilitate closure techniques such as long-range polymerase chain reaction (PCR).

the rare cutter sites. A scheme for aligning optical maps using Southern blotting has also been employed.[13–15,17]

3.3 Identification of Repeated Regions

In the absence of restriction maps, repeated regions can confound sequence assembly efforts. The number of repeats and their orientation is often difficult to determine using sequence assembly software. Clones thought to contain repeats can be optically mapped using a restriction enzyme which cuts within the repeat, enabling the number of repeats and their organization to be revealed.[36]

3.4 Identification of Genic Regions

Identifying coding sequences within mammalian genomes has proven both technically challenging and time-consuming, primarily because only small regions are transcribed; in the case of the complex human genome, 0.06%. The figure drops to 0.007% if purely exonic regions are considered.[37] Optical mapping can be used to screen for genes in mammalian genomes.[17] Expressed mammalian genes are characterized by a CG motif (CpG islands) which normally occurs at a low frequency in noncoding regions. CpG islands constitute a distinctive fraction of the genome because, unlike bulk DNA, they are nonmethylated and contain the dinucleotide CpG at its expected frequency. The average length of CpG islands is 1 kb and the haploid human genome is estimated to contain about 45 000 islands.[38] All human housekeeping genes and 40% of tissue-restricted genes are associated with CpG islands.[39] In total, only 57% of human genes have CpG islands, so unfortunately not all genes can be identified by CpG islands. Putative genes can be identified by optical mapping with enzymes which all have CpG in their recognition sequences such as *Not*I or *Eag*I. However, CpG islands may not be of such value in locating genes in microbial genomes since these often possess strikingly different A + T and G + C content compared to human DNA.

3.5 Optical Mapping for Population-based Genomic Studies

If high-resolution maps can be rapidly generated, microbial populations can be analyzed at the whole genome level. Whole genome maps from related strains can be aligned and differences in the maps can show regions where the genomes differ. With the sequence of one strain in hand, maps generated from the unsequenced strain can be compared to identify regions unique to the other strain which could be targeted for sequencing.

4 COMPARISON WITH OTHER PHYSICAL MAPPING APPROACHES

4.1 Gel Electrophoresis

The invention of PFGE in 1984[7] enabled large DNA molecules to be separated based on their size, and opened the door to physical mapping of whole chromosomes and genomes. Large DNA molecules digested with rare cutter restriction enzymes could be separated, generating a fingerprint, but determination of fragment order was still dependent on Southern blotting, generation of probes and hybridization of filters. Optical mapping, on the other hand, provides unambiguous fragment order without further manipulations. Fragments can be sized more accurately by optical mapping versus PFGE. Sizing accuracy for restriction fragments generated from BACs is comparable if not superior to conventional and PFGE.[10,40] Physical maps prepared by gel electrophoresis often fail to disambiguate repeats. Since optical mapping characterizes complex genomic regions at the level of single molecules, repeat complexities are discerned using restriction enzymes that cut once within a single repeating unit.

With a few notable exceptions, which include an eight-enzyme map of the *Escherichia coli* K12 genome[41] and physical maps of the *Saccharomyces cerevisiae* genome,[42,43] very few whole genome restriction maps have been constructed using electrophoretic approaches. High-resolution whole genome maps can be rapidly prepared by optical mapping. *Deinococcus radiodurans* and *Plasmodium falciparum* have been mapped and the fidelity of the maps was confirmed by sequencing of these genomes.[13,14,16,44] Microgram quantities of DNA are required to analyze DNA by electrophoresis. Since optical mapping analyzes DNA at the single molecule level, small amounts of starting material are required. This enables mapping of microorganisms, such as parasites, which are problematic to culture. For example, an optical map of the whole 30-mb *P. falciparum* genome was prepared using no more than 2 ng of genomic DNA.

Electrophoretic approaches are not amenable to full automation to include sample preparation and analysis. Gridding of samples on a single surface and development of object recognition via computer, ''machine vision'', has made optical mapping of cloned DNA a semi-automated process with the expectation that this type of development path can be extended to mapping of genomic DNA.

4.2 Fluorescent In Situ Hybridization

Fluorescent in situ hybridization (FISH) has emerged as a powerful approach for gene and chromosome level analyses in clinical cytogenetics.[45,46] FISH can be performed on metaphase chromosome spreads, interphase

nuclei[47,48] and decondensed ''halo'' DNA.[49] FISH is suitable for visualization of genetic aberrations affecting a few specific loci for which probes are available. However, its dependence on prior knowledge of genomic sequence makes it unsuitable for screening unknown genetic aberrations. FISH probes typically span 40–200 kb of genomic DNA.[50] Aberrations smaller than 10 kb cannot be reliably detected. Interphase FISH cannot estimate distances between hybridization markers greater than 100 kb.[51] Whole chromosome painting, multifluor FISH[46,52] and spectral karyotyping (SKY)[53] have enabled simultaneous visualization of up to 27 combinatorially labeled probes and this approach has revealed complex chromosome rearrangements not evident by conventional means.[52] Development of fiber FISH,[54,55] where the hybridization template consists of highly deproteinized chromatin aggregated together to form multistranded DNA fibers, has enabled probes as small as 200 bp to be used to map exonic regions on cosmid clones.[56] Such approaches could potentially be used to estimate numbers of duplicated expressed sequence tags (ESTs), or STSs examine chromosomal breakpoints in genomic DNA, or generate minimal tiling paths of clones.[54,57] Restriction fragments have also been used as fiber FISH probes to generate rudimentary restriction maps of large insert clones.[58] Short padlock FISH probes[59] can be amplified at the site of hybridization by a rolling-circle mechanism[60] and can be used to detect mutations.

Related approaches such as comparative genomic hybridization (CGH), which is a two-color hybridization of differentially labeled test and reference DNAs to normal human metaphase spreads[61] or DNA fibers,[62] and primed in situ labeling (PRINS), which is chromosome labeling performed by annealing of specific oligonucleotide primers followed by primer elongation by a *Taq* polymerase in the presence of labeled nucleotides,[63] are used predominantly for studying gene copy number aberrations in tumors and are limited to gross chromosomal changes such as deletions, translocations and amplifications.

In situ hybridization-based approaches and optical mapping are similar in requiring surface mounting of large intact DNA molecules. Extended DNA molecules are mounted for fiber FISH analysis by ''molecular combing'', whereby molecules attach at one end of the derivatized surface and are extended and aligned by a receding meniscus.[64,65] Limitations of these other approaches include low throughput, DNA fragmentation which prevents subsequent or simultaneous multimethod analyses, and difficulties in automation. These molecular approaches generally yield low resolution maps and were developed primarily for characterization of single loci, not entire genomes.[66,67]

4.3 Hybridization-based Microarrays

DNA probes can be gridded onto charged membrane surfaces[26–29] and modification of technologies from the photolithography and semiconductor industries enable oligonucleotide probes to be gridded at extremely high density creating microarrays on ''biochips''.[68,69] DNA samples labeled with fluorescent tags hybridize to homologous probes and the fluorescence intensity for each segment measured. Biochips are used to detect mutations, quantitate nucleic acids, and create gene expression profiles from different cell populations.[70–72] Although such hybridization-based approaches and optical mapping are both performed on surfaces and are amenable to high throughput by gridding of samples, this is where the similarities end. There is no underlying biochemical process in hybridization to probes. Biochips require prior knowledge of sequence whereas optical mapping can characterize unknown sequence. The hybridization on biochips is to short oligonucleotide DNA sequences[68,69] and the means by which biochips cover large genomic regions is by gridding of hundreds of thousands of probes on a single chip.[73] The number of samples that can be gridded on an optical mapping surface is limited first by the length of the molecules, which in the case of BACs can be in the order of microns, and second by the area on the surface which is required to generate sufficient fluid flow to stretch DNA molecules in the sample.

4.4 Other Single Molecule Approaches

Other single DNA molecule approaches have included visualization of single DNA molecules by fluorescence microscopy in solution,[74–76] and during gel electrophoresis,[75,77–79] restriction mapping of cosmid clones by atomic force microscopy of restriction enzymes bound to DNA,[80] visualization of DNA by scanning tunneling microscopy,[81] scanning force microscopy of circular DNA and DNA bending in transcription complexes,[82,83] direct mechanical measurement of the elasticity[84] and supercoiling of single DNA molecules using magnetic beads.[85,86] These approaches have been useful in characterizing structural and functional properties of single DNA molecules but have not found application in generating physical maps of genomes since applicability to automation and throughput are obstacles.

5 RECENT IMPROVEMENTS AND FUTURE DEVELOPMENTS

In order to map arbitrary sequences and gene locations, RecA-assisted restriction endonuclease (RARE)

digestion has been combined with optical mapping.[87] In this approach, DNA samples containing *Eco*RI sites are embedded in agarose inserts. RecA protein/oligonucleotide complexes bind to specific targets which contain *Eco*RI sites spanned by additional specific sequence of interest. Binding of the complex prevents the action of *Eco*RI methylase activity, which is used to methylate *Eco*RI sites which lack the specific oligonucleotide sequence. After RecA protein removal, the protected sites become the only non-methylated sites and are thus uniquely cleavable with *Eco*RI. The molecules are then mounted and mapped optically.

Restriction digests on surfaces are not the only biochemical reactions that can be assayed at the single molecule level. DNA polymerase I incorporation of fluorescently labeled nucleotides has been observed to occur on surface-mounted DNA molecules.[11] The action of DNA polymerases is quite different from that of restriction endonucleases. Restriction endonucleases bind their target, often with little distortion to the DNA helix.[88] In contrast, DNA polymerase I has a more complicated action. The enzyme binds to a nick site and then essentially wraps around the helix, using 5′-3′ exonuclease activity to remove bases, and 5′-3′ template addition to add new nucleotides.[89,90] Surface mounted molecules are therefore biochemically active. Severe adsorption of the DNA helix to the surface would preclude any meaningful degree of template addition or exonuclease activity.

Since optical mapping of genomic DNA has been used to analyze entire microbial genomes, similar approaches are being used to make a restriction map of the entire human genome. A pilot project to map the entire human genome using megabase-sized DNA molecules was recently completed. Molecules, directly extracted from peripheral blood, were mapped with *Pac*I. 0.6 human genome equivalents were mapped at 40-kb resolution, using genomic fragments with average size of 2.1 Mb. Analysis of the contigs formed showed good correspondence with suitably modified Lander–Waterman[19] physical mapping criteria in terms of the number and depth of overlapped genomic fragments. Goals are simultaneously to complete the human reference map to include 10–15 × coverage and to link with other physical maps by the alignment of restriction mapped BAC contigs. The utility of this map will be to facilitate assembly of sequence from the Human Genome Initiative. Optical mapping systems could potentially be used for large scale genomic analysis and as a means to perform population-based genomic studies such as analysis of human disease genes or characterization of breakpoints in tumors.

ACKNOWLEDGMENTS

The authors' work was supported in part by grants from the National Institutes of Health (HG-00225-08), the Department of Energy and the Burroughs Wellcome Fund.

ABBREVIATIONS AND ACRONYMS

APDEMS	3-Aminopropyldiethoxymethylsilane
APTES	3-Aminopropyltriethoxysilane
BAC	Bacterial Artificial Chromosomes
bp	Basepairs
CCD	Charge-coupled Device
CGH	Comparative Genomic Hybridization
ConVEx	Contig Visualization and Exploration Tool
DAPI	4,6-Diamidino-2 Phenylindole Dihydrochloride
DNA	Deoxyribonucleic Acid
ESTs	Expressed Sequence Tags
FISH	Fluorescent In Situ Hybridization
kb	Kilobases
Mb	Megabases
OMM	Optical Map Maker
PCR	Polymerase Chain Reaction
PFGE	Pulsed Field Gel Electrophoresis
PRINS	Primed In Situ Labeling
RARE	RecA-assisted Restriction Endonuclease
SIT	Silicon Intensified Target
SKY	Spectral Karyotyping
STS	Sequence Tagged Site
TE	Tris–Ethylenediaminetetraacetic acid
TESP	3-(Triethoxysilylpropyl)trimethyl-ammonium Chloride
YAC	Yeast Artificial Chromosomes
YOYO-1	Oxazole Yellow Homodimer

In recent years, there has been considerable interest in developing gene-targeting drugs. Synthetic molecules that bind effectively with high sequence specificity to a desired target in a particular ''destined'' gene sequence are of major interest in medicine and molecular biotechnological research. They show hope for the development of gene therapeutic agents, high-precision diagnostic devices for genetic analysis and convenient tools for nucleic acid manipulations. Peptide nucleic acid (PNA) is a nucleic acid analog in which the sugar–phosphate backbone of natural nucleic acid has been replaced by a synthetic peptide backbone usually formed from N*-(2-aminoethyl)glycine units resulting in an achiral and uncharged mimic. It is chemically stable and, in contrast to nucleic acids and peptides, is naturally resistant to hydrolytic (enzymatic) cleavage and thereby not expected to be degraded by cell extracts or inside a living cell. It is capable of sequence-specific recognition of DNA and RNA obeying a Watson–Crick hydrogen bonding scheme and the hybrid complexes exhibit extraordinary thermal stability and unique ionic strength effects. It also recognizes duplex homopurine sequences of DNA to which it binds by strand invasion, forming a stable PNA·DNA–PNA triplex with a looped-out DNA strand. This potential synthetic mimic of DNA, since its discovery in 1991, has attracted great attention within medicinal chemistry and molecular biology and also various other fields such as organic and physical chemistry because of its interesting chemical and physical properties. It has been regarded to have great potential for both diagnostic and pharmaceutical applications. In vitro studies have shown successful attempts to use PNA as an inhibitor for both transcription and translation of specific genes. This holds promise for using PNA for antigene and antisense therapy. However, the most exciting use of PNA, as an antisense or antigene drug, requires an efficient and safe method to deliver PNA into living cells, a problem that still remains to be solved.*

1 INTRODUCTION

Historically, PNA originates from attempts during the 1980s in the Danish organic chemist Ole Buchardt's laboratory to develop new DNA sequence-specific reagents. Based on the observation with flow linear dichroism (LD) that α-helical poly-γ-benzylglutamate (PBG) forms stacking complexes with aromatic chromophores, it was suggested that PBG with alternating nucleobases and acridine moieties instead of phenyls might bind sequence selectively to duplex DNA by combined Hoogsteen base-pair (bp) formation and intercalation with the helix backbone in the major groove. The suggested compound was tentatively named *peptide nucleic acid, PNA*.

Today's PNAs (Figure 1a and b) are DNA analogs in which generally a 2-aminoethylglycine linkage replaces the normal phosphodiester backbone.[1,2] A methyl carbonyl linker connects standard (in some case unusual) nucleotide bases to this backbone at the amino nitrogens. The nonprototype, yet interesting, chemistry of this synthetic molecule has three important consequences: peptide nucleic acids are neutral molecules, they are achiral and they are not susceptible to any hydrolytic (enzymatic cleavage). Despite these great differences from DNA, PNA is capable of sequence-specific recognition of DNA and RNA obeying the Watson–Crick hydrogen bonding rules[3,4] and the hybrid complexes thus formed exhibit extraordinary thermal stability and unique ionic strength properties. Regarding applications of PNA, one obvious question is what the advantage is

of using PNA over DNA. Scientists have been working towards the development of a wide range of applications for PNAs since 1991.[1] These can be generalized in four categories: first, its use as a tool for molecular biology and biotechnology;[5–9] second, towards the development of a gene-targeted drug using antigene or antisense strategy;[10–12] third, the use of PNA for diagnostics purpose and towards the development of biosensors;[13–16] and fourth, the study of basic chemistry to address the problems related to improvement of PNA.[17–20] As we review PNA applications, we shall focus on various analytical techniques necessary for the synthesis and characterization of novel PNA constructs, their development and application as gene therapeutic agents and detection systems for genetic analysis, and finally on understanding the physicochemical aspects of PNA and PNA–nucleic acid complexes.

2 CHEMICAL METHODS – CHEMISTRY AND SYNTHESIS

2.1 Synthesis

The backbone of PNA carries 2-aminoethylglycine linkages to replace the normal phosphodiester backbone of DNA.[1,2] The nucleotide bases are connected to this backbone at the amino nitrogens through a methylene carbonyl linker (Figure 1a and b). Since PNAs are achiral molecules, there is no need to develop a stereoselective pathway for their synthesis. PNA oligomers are prepared following the well-established solid-phase peptide synthesis protocols.[21,22] The protecting scheme for the amino groups of PNA monomers is based on either Boc or Fmoc chemistry.[23–25] In principle, PNA oligomers are synthesized using standard solid-phase peptide synthesis procedures with a (methylbenzhydryl)amine polystyrene resin as the solid support.[23,26,27] Several modifications of PNA, related to various functional requirements, have been reported.[27] It is possible to modify PNA oligomers either by coupling amino acids during solid-phase synthesis or by attaching compounds that contain a carboxylic acid group to the exposed N-terminal amine group. The postsynthetic modification process employs coupling to an introduced lysine or cysteine residue in the PNA.[23,27] A bis-PNA is prepared in a continuous synthesis process by connecting two PNA segments via a flexible linker composed of multiple units of either 6-aminohexanoic acid or 8-amino-3,6-dioxaoctanoic acid.[28] It has been reported that changing cytosine to pseudoisocytosine in the Hoogsteen strand abolishes the pH dependence of a DNA·PNA–DNA triplex without affecting the stability of the triplex.[28]

2.2 Purification

Postsynthesis procedures involve cleaving PNA oligomers from the solid support by treatment with either anhydrous hydrogen fluoride or trifluoromethanesulfonic acid, as done in traditional peptide chemistry, followed by high-performance liquid chromatography (HPLC) purification.[23–30] In some cases, crude PNA products are cleaved from the solid matrix by treatment with trifluoroacetic acid–*m*-cresol (4 : 1) and precipitated in ice-cold diethyl ether and thereafter dissolved in 0.1% trifluoroacetic acid solution.[23,29,30] PNA molecules are further purified and characterized by reversed-phase HPLC followed by matrix-assisted laser desorption ionization/time-of-flight mass spectrometry (MALDI/TOFMS).[23,28–30] We shall discuss this later.

3 ELECTROPHORETIC AND HYBRIDIZATION TECHNIQUES

PNAs can hybridize to complementary DNA and RNA sequences in a sequence-dependent manner obeying the Watson–Crick hydrogen bonding scheme. A unique multiple-stranded triplex structure containing both Watson–Crick and Hoogsteen base pairing is also possible from a 2 : 1 PNA–DNA complex.[31–34] The mechanistic pathway for the formation of the triplex is known as ''strand-invasion''. PNA–DNA hybridization is more affected by base mismatches than corresponding DNA–DNA hybridization. Surprisingly, PNA can maintain sequence discrimination up to the level of a single mismatch. High-affinity binding, a high level of mismatch discrimination and the novel strand-invasion property have allowed researchers to develop several PNA-based applications, employing the basic principles of electrophoresis and hybridization, in conjunction with molecular biology/biotechnology, medicine (as gene-targeted drug) and diagnostics.

3.1 PNA as a Tool for Molecular Biology/Biotechnology Research

The following applications evidence the potential of PNAs as a tool for molecular biology and biotechnology

and justify the development of new methodologies related to that.

3.1.1 PNA Hybridization as an Alternative to Southern Hybridization Technique

Southern hybridization is perhaps one of the most widely used techniques in molecular biology. It is used to analyze genetic loci, employing fragments of defined length obtained from either polymerase chain reaction (PCR) or restriction digestion. The great utility of this core molecular biological technique is derived from its ability to predict both size and sequence information and information regarding the genetic context. However, the disadvantages of this process include laborious multistep washing steps and poor sequence discrimination between closely related species.

PNA pregel hybridization simplifies the process of Southern hybridization and eliminates the cumbersome postseparation, probing and washing steps. It is possible to use labeled (fluoresceinated) PNA oligomers as probes and hybridize them to a denatured DNA sample at low ionic strength, and the mixture is thereafter directly subjected to electrophoresis for size separation. Single-stranded DNA fragments are separated on the basis of their length. The charge-neutral backbone of peptide nucleic acid allows for hybridization at low ionic strength and renders a much higher mobility to the complex compared with the excess unbound PNA. The hybrids are blotted (transferred) on to a nylon membrane, dried, ultraviolet (UV) cross-linked and detected using standard chemiluminescent techniques.[8] It is also possible to detect the bound PNA by direct fluorescence detection using capillary electrophoresis (CE) (to be discussed later). The strong binding of PNA to DNA allows the PNA–DNA duplex to remain intact under conditions where the normal DNA–DNA duplex tends to disrupt. This allows sequence-specific detection with simultaneous size separation of the target DNA following a simple and straightforward protocol. Consequently, the analysis is much faster than conventional Southern hybridization technique.

3.1.2 Nucleic Acid Purification

PNAs have also been used to purify target nucleic acids. The purification process is based on its unique hybridization property. PNAs carrying six histidine residues can be used to purify target nucleic acids by nickel affinity chromatography.[6] Biotinylated PNAs in combination with streptavidin-coated magnetic beads may be used to purify *Chlamydia trachomatis* genomic DNA directly from urine samples. Inspite of being simple, fast and straightforward, this ''purification by hybridization'' approach has a number of drawbacks. First, it requires knowledge of a target sequence and depending upon that a capture oligomer has to be synthesized for each different target nucleic acid. Since the target sequences for the short pyrimidine PNA, the most efficient probe for strand invasion, are prevalent in large nucleic acids, such short PNAs can be used as generic capture probes for purification of large nucleic acids. It has been shown that a biotin-tagged PNA–thymine heptamer could be used to purify efficiently human genomic DNA from whole blood by a simple and rapid procedure.

3.1.3 Enhanced Polymerase Chain Reaction Amplification

PCR is used to amplify unique regions of DNA so that they can be detected in large genomes. PCR, now widely used in research laboratories and hospitals, relies on the ability of DNA-copying enzymes to remain stable at high temperatures. The three steps in the PCR (carried out in the same vial), viz. the separation of the strands, annealing the primer to the template and the synthesis of new strands, take less than 2 min. At the end of a cycle, each piece of DNA in the vial has been duplicated. Each newly synthesized DNA piece can act as a new template, so after 30 cycles, 1 million copies of a single piece of DNA can be produced. Taking into account the time it takes to change the temperature of the reaction vial, 1 million copies can be ready in about 3 h.

PCR has been widely used for various applications including the amplification of variable number of tandem repeat (VNTR) locus for the purpose of genetic typing.[35,36] However, in some cases there are preferential amplifications of small allelic products relative to large allelic products. This results in an incorrect typing in a heterozygous sample.[37] PNA has been used to achieve an enhanced amplification of VNTR locus D1S80.[7] This renders a genetic pattern which is fairly easy to decipher. Small PNA oligomers are used to block the template. This makes the latter unavailable for interstrand and intrastrand interaction during reassociation. However, the primer extension is not hindered. During primer extension, polymerase displaces the PNA molecules from the template and extends the primer to completion. This application demonstrates the potential of PNA for PCR amplification where fragments of different sizes are more accurately and evenly amplified. As the probability of differential amplification is less, the risk of misclassification is greatly reduced.

A recent report by Misra et al.[38] has demonstrated that PNA–DNA chimera[39] lacking the true phosphate backbone can actually act as a primer for the polymerase reaction catalyzed by DNA polymerases. The analog, $(PNA)_{19}$-T_PG-OH, consists of 19 bases in the PNA part followed by a dinucleotide (T_PG-OH) with a single

phosphate and a free 3′-OH terminus. This chimera, when annealed with a complementary RNA or DNA template strand, can be used as an efficient primer to catalyze the addition of nucleotide by polymerase enzymes. The primer is recognized by two reverse transcriptases and also by the Klenow fragment of *Escherichia coli.* DNA polymerase I. From the results it has been proposed that the phosphate backbone of the template primer may not be essential, at least not in this case, for recognition and binding by the polymerases. The results also suggested that the diameter of the duplex region is a more critical factor than the phosphate backbone regarding the template-primer reaction and accommodating the same within the binding domain of the enzyme.

3.1.4 PNA and S1 Nuclease as Artificial Restriction Enzymes

S1 nuclease degrades single-stranded nucleic acids releasing 5′-phosphoryl mono- or oligonucleotides. The enzyme is basically a glycoprotein with a carbohydrate content of 18%. It is extensively used to remove the single-stranded overhangs of DNA fragments, RNA transcript mapping and construction of unidirectional deletions. PNA in combination with S1 nuclease can act as an ''artificial restriction enzyme'' system. Homopyrimidine PNA oligomers can hybridize with the complementary targets on dsDNA via a strand invasion mechanism, leading to the formation of looped-out noncomplementary DNA strands. Upon treatment by nuclease S1, the single-stranded DNA part is cut into well-defined fragments. The binding of two PNAs to two adjacent targets, on either the same or opposite DNA strands, essentially opens up the entire region making the substrate more accessible for the nuclease digestion and thereby increasing the cleavage efficiency.[5]

3.1.5 PNA-assisted Rare Cleavage

Peptide nucleic acids, in combination with methylases and other restriction endonucleases, can act as rare genome cutters.[9] The technique, called the PNA-assisted rare cleavage (PARC) technique (Figure 2), employs the strong and sequence-specific binding of PNAs, preferably bis-PNAs, to short homopyrimidine sites on large DNA molecules, e.g. yeast or λ DNA. The PNA binding site is selected in such a fashion that it overlaps with the methylation/restriction enzyme site on the DNA. When bound to DNA, this PNA molecule will efficiently shield the site from enzymatic methylation whereas the other so-called naked or unprotected methylation/restriction sites will be methylated. After the removal of bis-PNA, it is possible to cleave the whole DNA by restriction enzymes into a limited number of pieces. DNA is efficiently

Figure 2 Schematic representation of the PARC technique. The symbols ——, and ■ represent PNA binding site, restriction enzyme site and methylated restriction enzyme site, respectively. Methylated sites are not subjected to a restriction digestion.

protected from enzymatic digestion due to methylation in most of the sites and is only cleaved through those sites which were previously bound to PNA. Thus, short PNA sequences, particularly positively charges bis-PNAs, combined with various methylation/restriction enzyme pairs, are capable of providing a new class of genome rare cutters.

3.1.6 Determination of Telomere Size

The standard procedure for the determination of telomere length involves Southern blot analysis of genomic DNA and provides a range for the telomere length of all chromosomes present. Another approach includes the use of fluorescein-labeled oligonucleotides and monitor the in situ hybridization of them to telomeric repeats. Much better and more quantitative results are obtained when DNA oligonucleotides are replaced by fluorescein-labeled PNAs, as shown by Lansdorp et al.[40] This PNA-mediated approach allows accurate estimates of the telomeric length to be made. In situ hybridization of fluorescein-labeled PNAs to telomeres is faster than to DNA hybridization and requires a lower concentration of the probe. Low photobleaching and an excellent signal-to-noise ratio make it possible to quantitate telomeric repeats on individual chromosomes in this way. It is likely that variations of this approach can be applied to other repetitive sequences to achieve similar results.

3.2 Possible Applications of PNA in Medicine

The potential of PNA to act as a genetic drug has been well appreciated. It is clearly a substantial lead in gene therapeutic drug design provided that we have well-identified targets for it. Two general strategies

Figure 3 Antigene and antisense strategy: cells can be treated with an antigene oligonucleotide (such as PNA), which can bind to a (specific) complementary sequence in the DNA and inhibits transcription of the gene. On the other hand, an antisense oligomer can hybridize to a specific mRNA sequence to inhibit the expression of a protein at the level of translation.

are applicable towards gene therapeutic drug design (Figure 3). Oligonucleotides or their potential analogs can be designed to recognize and hybridize to complementary sequences in a particular gene and they can interfere with transcription of that particular gene (antigene strategy). Alternatively, analogs can be designed to recognize and hybridize to complementary sequences in mRNA and thereby inhibit its translation (the antisense strategy). Peptide nucleic acids are biologically and chemically stable and have significant effects on replication, transcription and translation, as revealed from in vitro measurements. Moreover, so far no signs of general toxicity of PNA have been observed. PNA binding to mRNA interferes with translation, PNA–dsDNA strand displacement complexes inhibit protein binding and block RNA polymerase elongation.

3.2.1 Transcription Arrest by PNA: the Antigene Effect

Homopyrimidine PNAs form extremely stable strand-displacement complexes upon binding to dsDNA. In principle, they should be capable of working as antigene agents. In reality, such complexes are indeed capable of affecting the process of transcription involving both prokaryotic and eucaryotic RNA polymerases in vitro. PNA bound to a promoter region is capable of blocking the DNA access of the corresponding polymerase protein. PNA strand-displacement complexes, located far downstream from the promoter, can also efficiently block polymerase progression and transcription elongation and thereby produce truncated RNA transcripts. This requires that the PNA target, i.e. the DNA polypurine target, must be present in the gene of interest. It has been found that even an 8-mer PNA (T_8) is able to block phage T_3 polymerase in action.[41] The effect of having a PNA target within a promoter region on gene expression has been demonstrated for IL-2Rα gene.[10,42] The PNA_2–DNA triplex thus can arrest transcription in vitro and can act as an antigene agent. However, one of the major obstacles to applying PNA as an antigene agent is that the strand invasion or the formation of strand displacement complex occurs very slowly at physiological salt concentration.[43,44] Several modifications of PNA have shown improvement in terms of binding. Modifications of PNA by the incorporation of intercalators,[45] positively charged lysine residues,[28,46] chemically linking the ends of the Watson–Crick and Hoogsteen PNA strands to each other[28] or pH-independent pseudoisocytosines into the Hoogsteen strand[28] can drastically increase the association rates with dsDNA. A recent report by Lee et al.[47] has demonstrated that PNA as well as the PNA–DNA chimera complementary to the primary site of the HIV-I genome can completely block priming by $tRNA_3^{lys}$ and consequently the in vitro initiation of the reverse transcription by HIV-1 RT. Their observations suggest that oligomeric PNAs targeted to various critical regions of the viral genome are likely to have a strong therapeutic potential for interrupting multiple steps involved in the replication of HIV-1.

It has been found that under physiological salt conditions, binding of PNA to supercoiled plasmid DNA is faster than linear DNA.[44,46] This indicates that the topology of DNA is an important factor or criterion for determining the binding rate. Since transcriptionally active chromosomal DNA is usually negatively supercoiled, this could be of relevance for PNA binding in vivo. It has also been shown that binding of PNA to dsDNA is enhanced when the DNA is being transcribed. Such transcription-mediated PNA binding occurs three times as efficiently when the PNA target is situated on the nontemplate strand than on the template strand. As transcription mediates template strand-associated complexes which arrest further elongation, the action of RNA polymerase results in repression of its own activity, i.e. *suicide transcription*.[48] These findings are highly relevant for the possible future use of PNA as an antigene agent.

It is important to mention that there are also reports regarding the ability of PNA to activate transcription which, however, is not related to its antigene effect. It has been demonstrated that the looped-out single-stranded structure formed as a result of strand invasion can also act as efficient initiation sites for *E. coli* and mammalian RNA polymerases in which the polymerase might start transcription using the single-stranded loop as a template.[49] This is consistent with the affinity of RNA polymerase for single-stranded DNA and its ability to transcribe single-stranded DNA.

3.2.2 Translation Arrest by PNA: the Antisense Effect

The principal mechanism of antisense effects by oligodeoxynucleotides is believed to be either a ribonuclease H (Rnase H)-mediated cleavage of the RNA strand in oligonucleotide–RNA heteroduplex or a steric blocking of the translation machinery at the oligonucleotide–RNA complex.[50] Oligodeoxynucleotide analogs, such as phosphorothioates, activate RNase H and thus hold the promise of working as efficient antisense agents. However, they have also been shown to exhibit nonspecific effects. PNA–RNA duplexes, on the other hand, cannot act as substrates for RNase H. Therefore, the antisense activity of PNA has to be dependent on other mechanisms. In fact, the antisense property of PNA is based on the steric blocking of either RNA processing, transport into cytoplasm or translation. In vitro translation experiments involving rabbit reticulocyte lysates have shown that both duplex- (mixed sequence) and triplex-forming (pyrimidine-rich) PNAs are capable of inhibiting translation at targets overlapping the AUG start codon.[50] Triplex-forming PNAs are able to hinder the translation machinery at targets in the coding region of mRNA. However, translation elongation arrest requires a $(PNA)_2$–RNA triplex and thus needs a homopurine target of 10–15 bases. However, duplex-forming PNAs are not capable of this. Triplex-forming PNAs can inhibit translation at initiation codon targets and ribosome elongation at codon region targets.

A recent report by Mologni et al.[51] has demonstrated the effects of three different types of antisense on the in vitro expression of PML/RARα gene. The first one was complementary to the first AUG (initiation) site. The second one was capable of binding to a sequence in the coding region that includes the second AUG, the starting site for the synthesis of an active protein. The third PNA was capable of binding to the 5′-untranslated region (5′-UTR) of the mRNA, the point of assembly of the translation machinery. These three PNAs provided an efficient inhibition when used together even at concentration much below the critical concentration used for each individual. This indicates that the PNA targeting of RNA molecules such as PML/RARα require effective blocking of different sequences on the 5′ part of the messenger. A 5′-UTR PNA target can be used as efficiently as an AUG target to achieve an antisense activity of PNA and a more effective translation inhibition can be achieved by combining PNA directed towards 5′-UTR and AUG regions.

3.2.3 Cellular Effects and Delivery of PNA

It is important to add here a few lines regarding the effect of PNA on intact cells and problems related to its delivery. Effects of PNAs on intact cells have only been demonstrated upon cellular microinjection and an antisense activity against a transfected gene has been established in this way.[10,18] However, the cellular uptake of PNA is very poor, which is still considered the major obstacle against the prospective use of PNA as a gene therapeutic drug. Efforts are being made to increase the cellular uptake of PNA, especially by modifying the molecule itself or by conjugating suitable ligands, which will result in an enhanced physical or receptor-mediated cellular uptake. Incorporation of ''guide'' sequence or some ''vector'' peptides might make it more attracted to the cell membrane and will eventually help in docking the desired PNA at the cell surface. A recent report by Aldrian-Herrada et al.[52] showed that a peptide nucleic acid is more rapidly internalized in culture neurons when coupled to a delivery peptide (retro-inverso peptide). A PNA antisense for the AUG translation initiation region of prepro-oxytocin mRNA was coupled to the vector retro-inverso peptide. The conjugated construct was internalized by cultured cerebral cortex neurons within minutes. Penetration of single PNA molecules was rather slow. It has been found that both PNA and the peptide–PNA construct lowered

the amounts of mRNA coding for prepro-oxytocin in these neurons. This shows that PNAs guided by suitable vector peptides can act as powerful antisense agents.

Another strategy which has been adapted to improvise the delivery of PNA is to incorporate it into some kind of delivery vehicles (vesicles), e.g. liposomes. However, the assessment of the latter method has to await tests in a real in vivo system involving animal models.

3.3 PNA as a Diagnostic Tool

Nucleic acid hybridization forms the basis for the diagnosis of inherited or infectious diseases. High-affinity binding of PNA oligomers to its complementary sequences provides a clear advantage for molecular recognition and leads to the development of new applications of PNA, especially as a diagnostic probe for detecting genetic mutations. Based on its unique hybridization property, a number of applications have been described utilizing PNA as a probe for the detection of genetic mutation and mismatch analysis.

In this section, we describe some of the developments related to the use of PNA as a probe to detect genetic mutation and corresponding mismatch analysis, confirming its potential as a diagnostic tool for different clinical applications. Fundamental principles related to each of these applications will also be discussed.

3.3.1 Single Base-pair Mutation Analysis Using PNA-directed Polymerase Chain Reaction Clamping

Amplification of the target nucleic acid to detectable quantities by the PCR technique is an important step regarding the detection of genetic diseases, especially those related to the single base pair mutations. The higher specificity of PNA binding to its complementary nucleic acid, higher thermal stability of a PNA–DNA duplex compared with the corresponding DNA–DNA duplex and its inefficiency to act as a primer for DNA polymerases are the basis for novel methodology. Figure 4 depicts the schematic representation of the PCR cycle and the strategy employed for this PNA-directed PCR clamping. This procedure includes a distinct annealing step involving the PNA targeted against one of the PCR primer sites. This takes place at a temperature higher than that for PCR primer annealing and thus PNA is selectively bound to the DNA molecule. The PNA–DNA complex formed at one of the primer sites can effectively block the formation of a PCR product. It was also found that PNA is able to discriminate between fully complementary and single mismatch targets in a mixed target PCR. Sequence-selective blockage by PNA

Figure 4 Mutation analysis using PNA-directed PCR clamping: schematic representation of the strategy for the PCR cycle involving PNA-directed clamping. In case of the normal (wild type) DNA, the bound PNA will sterically hinder annealing of a partially overlapping primer sequence, thus preventing the normal sequence from appropriate PCR amplification. In the case of mutant alleles, the melting temperature of the PNA/DNA is reduced and the primer can outcompete PNA annealing to carry on preferential amplification of mutant sequences.

allows suppression of target sequences that differ by only one base pair. Also, this PNA clamping was able to discriminate three different point mutations at a single position, as demonstrated in a model system by Örum et al.[13]

Based on the principle of PNA-mediated PCR clamping,[13] a study by Thiede et al.[15] has demonstrated a novel approach for simple and sensitive detection of mutations in the *ras* proto-oncogenes. The strategy behind this is schematically represented in Figure 4. Chromosomal DNA is hybridized to a 15-mer PNA complementary to a normal wild-type sequence surrounding codons 12 and 13. In the case of the normal Ki-*ras*, formation of a PNA–DNA duplex will be favored owing to its high melting temperature and thus it would sterically hinder the annealing of overlapping oligonucleotides. Hence normal Ki-*ras* sequences will not be sufficiently (PCR) amplified. On the other hand, the melting temperature of the mutated hybrid sequence is much lower than the corresponding normal one. Hence the binding of primer oligonucleotide will be relatively favored to outcompete PNA annealing. Hence the mutated sequence will be preferentially amplified.

One of the major advantages of this PNA mediated PCR clamping is that it allows the detection of mutations stretched over 4–6 bp regions in a single reaction and this could also be used to detect other hot-spot mutations.[13,15]

3.3.2 *Screening for Genetic Mutations by Capillary Electrophoresis*

Most of the powerful separation techniques for biomolecules are based on electrophoresis, i.e. the migration of electrically charged species in solutions under the influence of an electric field. In principle, to achieve the separation of two species, their electrophoretic mobilities, μ, must be different. The mobility, μ, is given by Equation (1):

$$\mu = \frac{v}{E} = \frac{Q}{f} \tag{1}$$

where v and Q are the electrophoretic velocity and the electrophoretic charge of the analyte, respectively, E is the electric field strength and f is the friction coefficient. For DNA in free solution, both Q and f are proportional to the contour length of the DNA, say L_c. In fact, it has been experimentally verified that in free solution the mobility is independent of the DNA size. A size-dependent mobility is generally obtained by using a separation medium such as a gel or a polymer solution. Instead of using a separation medium, a size-dependent mobility of DNA can also be obtained by breaking the scaling symmetry between the electrical and frictional forces either by changing the charge or the mass distribution. The electrophoresis in slabs of polyacrylamide or agarose gels has been the preferred method for separation of DNA for a long time. In recent years, especially owing to technological advances, there has been considerable interest in CE of DNA.

In CE,[53–55] separation takes place in a long, thin capillary (typically 50–80 cm long, inner diameter ~10–300 μm), generally made of fused silica. A portion of the coating is removed at the end of the capillary to detect the analyte. As the analyte passes the detection window it can be visualized by UV or laser-induced fluorescence (LIF) detection which is accomplished on-line and can be automated. CE is capable of analyzing minute amounts of sample (typically of the order of picograms to femtograms). However, the major disadvantage compared with slab-gel electrophoresis is that generally it is not possible to analyze more than one sample at a time.

The most important phenomenon described in CE is known as electroosmosis, an electrokinetic effect described as the motion of a liquid relative to a fixed charged surface caused by an electric field. Under the influence of an aqueous solution, the silica surface of the fused-silica capillaries forms silanol groups ($SiOH_2^+$, SiOH or SiO^-). This depends upon the pH values and for a pH value above 3–4, the silica surface will be negatively charged. These negative charges are counterbalanced by positive ions from the surrounding solution, forming an electrical double layer close to the surface (Figure 5).

Figure 5 Illustration of the Stern–Gouy–Chapman model of the electrical double layer at the interface between the capillary wall and the electrolyte system. The arrows indicate the direction of electroosmotic flow through the capillary. *Note*: acidic silanol groups impart a negative charge on wall and counterions migrate towards cathode, dragging solvent along.

According to the model described by Stern, Gouy and Chapman,[56] the electric double layer can be described as consisting of one inner, static layer of adsorbed counterions, known as the Stern layer, and an outer, mobile layer in which ions diffuse due to thermal motion, known as the Gouy–Chapman layer. When an electric field is applied over the capillary, the positive ions migrate towards the negative electrode, dragging the mobile liquid layer with them. Although the electric double layer is only about 100 Å thick, the electroosmotic flow is transmitted throughout the whole cross-section of the capillary. In electrically driven systems, the flow caused by electroosmosis shows a uniform velocity across the capillary diameter except in the double layer region close to the wall where the flow velocity approaches zero. This so-called plug-flow appears as a result of the uniform distribution of the driving force for electroosmosis along the entire length of the capillary. For a particular field strength, the magnitude and direction of the electroosmotic flow depend on the composition of the capillary surface and on the pH and ionic strength of the electrolyte solution. Owing to the strong electroosmotic flow towards the cathode, all species, irrespective of their charge, move towards the negative electrode. Thus positively and negatively charged species can be analyzed in the same run. As the electrophoretic mobility of a free polyelectrolyte (DNA) is independent of molecular weight because the electric driving force and the frictional force are both proportional to the length (Equation 1), it may appear that electrophoresis in free solution is not a convenient tool for DNA separation. However, if the scaling symmetry between electrical and frictional

forces can be disrupted, by changing either the charge or mass distribution or the hydrodynamics, a size-dependent mobility can be achieved for DNA.

Carlsson et al.[14] reported a novel, diagnostic method for the detection of genetic mutation using PNA as a probe for CE. The method is based on the unique hybridization of PNA and is sensitive enough to detect a single mismatch in the sample DNA. The model system consisted of four 50-mer single-stranded DNA fragments, one wild type and three mutant sequences (Table 1), representing a part of the cystic fibrosis transmembrane conductance regulator gene (CFTR). The probe was a 15-mer PNA oligomer with a sequence complementary to the wild-type sequence. The principle of the method is that PNA only binds to the DNA in the absence of any mutation in the particular region of the CFTR gene and it is possible to detect the presence of such a hybrid duplex using free solution CE. Separation of PNA–DNA duplexes was carried out at a high temperature (~70 °C) (Figure 6a–c) and 50 mM ionic strength. At this temperature and ionic strength, only the hybrid duplex carrying the wild-type DNA sequences will be detected. The hybrid complex carrying single-mismatch DNA will be melted. Free PNA is not detected because it binds to the capillary wall. In another experiment, the PNA probe was added to a PCR preparation of the 142-mer wild-type CF fragments and the 139-mer three-base deletion fragments. When studied at 50 °C, the PNA–DNA duplex was identified for the wild-type sequences but was not seen at all for the mutant.

In another study Nordén and co-workers. (unpublished observations) used free solution CE to detect point mutation in a 15-mer DNA fragment, which represents a vulnerable part of the p53 gene. The PNA probe used for this study was a 15-mer oligomer having sequence complementary to the wild-type p53 DNA (in this case the 15-mer DNA). The separation was carried out at a temperature below the thermal melting temperature, as determined from UV spectrophotometry, of the fully matched PNA–DNA hybrid, but above the thermal melting temperature of the PNA–DNA duplex carrying a single mismatch at the eighth position (corresponding to a mutation in the codon 175 of the p53 resulting in an altered P53 protein with an arginine replaced by a histidine). At this temperature, the fully matched duplex maintained its structural integrity and was detected by using UV or LIF

Figure 6 Free-solution CE of a mixture of PNA and DNA that has a single-base substitution in the recognition region (MU1, Table 1) at (a) 50 and (b) 70 °C. (c) Electropherogram at 70 °C of a mixture of PNA and the wild-type DNA sequence. At 70 °C, PNA cannot remain bound to the mutant DNA sequence and the peak corresponding to that hybrid duplex will not appear in the electropherogram. (Figure adapted by permission from Carlsson et al.[14])

detection. By contrast, as the PNA probe could not bind to the single-mismatch DNA sequence at this temperature, hence no peak corresponding to this duplex was noticed. In this way, the method has the capability to detect single-base substitutions. One great advantage of using PNA instead of DNA as a hybridization probe is that it gives a more efficient sequence discrimination and allows separation at high temperature, where DNA–DNA hairpin structures, responsible for band compression in gel electrophoresis, are eliminated.

More sensitive detection can be achieved by using PNA probes with a fluorescence tag, which requires only a very low concentration of the sample. If studied at high temperature, LIF detection will only produce a signal for the bound PNAs. In future, it might be possible to establish a universal screening strategy for any genetic disease with a known spectrum of mutations by developing a PNA probe library, possibly utilizing multiple fluorescence tags for multiplex testing of one or more exons.

Rose[57] reported the characterization of antisense binding properties of PNAs using capillary gel electrophoresis (CGE). Like free solution CE, only a minute amount (femtomoles) is required for the analysis. A known amount of PNA is mixed with an aliquot of an oligonucleotide stock solution and a portion of the mixture is introduced into the gel column of the capillary. The sample is then allowed to migrate through the column under the influence of an applied electric field. The area of the separated components is measured as a function of elapsed time after mixing of oligonucleotide-to-PNA ratio. Compared with free solution CE, this method shows a stronger dependence on mass. The ability of this method to resolve free and bound PNA allows the measurement of relative binding kinetics using gel-filled capillaries. This method is also useful for studying the interaction chemistry of antisense oligonucleotides as the separation mechanism of the CGE, i.e. the mobility of the experimental sample through a gel medium acting as a sieve, and permits the separation of the free oligomer from the bound species.

It is appropriate in this section to mention another gel-based technique, known as affinity electrophoresis. Affinity electrophoresis, depending on the noncovalent interaction of two species, requires the immobilization of one of the interacting species in a gel matrix.[58] It has been found that the entrapped PNA causes a retardation of the complementary oligonucleotides. PNA entrapped in a gel matrix allows specific hybridization during electrophoretic passage of a complementary DNA. Owing to the high affinity between PNA and DNA, the retardation of DNA is directly related to the binding of PNA through complementarity. This affinity electrophoresis permits the visualization of hybridization between an immobilized PNA and complementary DNA, migrating in an electric field, in real time. Moreover, a more sensitive detection of a reasonable number of samples in real time is possible by using LIF detection employing fluorescent samples.

3.3.3 PNA as a Probe for Nucleic Acid Biosensor

DNA biosensor technology, based on a very simple principle, holds promise for rapid and cost-effective detection of specific DNA sequences. A single-stranded probe oligonucleotide is immobilized onto optical, electrochemical or mass-sensitive transducers to detect the complementary (or mismatch) strand in a sample solution. The response from the hybridization event is converted into a useful electrical signal by the transducer. PNA, owing to its strong sequence-specific hybridization with DNA, can be used as the recognition layer in DNA biosensors. We describe here the use of PNA as a probe for sequence-specific biosensors.

3.3.3.1 BIAcore Technique: Kinetic Study and Mismatch Analysis It is possible to assess the kinetic parameters of PNA hybridization and make mismatch analysis using a BIAcore (biomolecular interaction analysis) instrument.[59] The system is generally used for studying real-time BIA using optical detection technology. The core part of the instrument is a sensor chip (surface) on which the real-time interactions are monitored. In BIA measurements, the probe molecule is directly attached to the surface and the analyte molecule is free in solution. The detection principle in BIA utilizes surface plasmon resonance (SPR). The response signal of the BIAcore apparatus is proportional to the change in the refractive index at the surface and is assumed to be proportional to the mass of substance bound to the chip. The important point is that this technique does not require any labeling of the interacting component and the response is primarily independent of the nature of the molecules. In a real-time BIA measurement, it is possible to monitor the changes in the surface concentration on a timescale of the order of 0.1 s, which, in principle, is sufficient enough to determine typical biomolecular kinetic rate constants in the range 10^3–$10^6\ M^{-1}\ s^{-1}$ (association) and 10^{-1}–$10^{-5}\ s^{-1}$ (dissociation).

Jensen et al.,[60] for the first time, reported an investigation of PNA–DNA/RNA hybridization using the BIAcore technique. The sensor chip used in this case was basically a thin gold surface covered with a layer of dextran that contained streptavidin chemically coupled to the dextran (Pharmacia sensor chip SA5). A biotinylated PNA [biotin-$(eg1)_3$-TGTACGTCACAACTA-NH_2; N- to C-terminal; note: PNA is generally written from N- to C-terminal] was used as a probe and it was immobilized to the streptavidin chip by employing the strong

coupling between biotin and streptavidin. By measuring the amount of bound substance (fully complementary and also various singly mismatched RNA and DNA oligonucleotides) as a function of time when a solution containing the complementary strands passes over the chip surface, the association kinetics were studied. The dissociation was correspondingly monitored by detecting the time dependence of the mass decrease as the surface was subsequently washed with buffer. It is also possible to regenerate the PNA surface by washing with HCl to remove the remaining hybridized products and perform consecutive studies with the same immobilized PNA. Assuming a two-state model, $A + B \rightleftharpoons AB$, the analysis of the hybridization kinetics was carried out. The dissociation kinetics, obtained from the dissociation part of the sensorgram (Figure 7), were analyzed using Equation (2):

$$[AB] = [AB]_0 e^{-k_d(t-t_0)} \tag{2}$$

where $[AB]_0$ represents the duplex concentration at time t_0 and k_d is the dissociation rate constant. The association kinetics were analyzed with respect to the concentration dependence of the association rate by varying the concentration of the analyzed agent, A, in the mobile phase (Equation 3):

$$[AB] = \left\{ \frac{k_a[A][B]_0}{k_a[A] + k_d} \right\} \quad 1 - e^{-(k_a[A]+k_d)t} \tag{3}$$

Using $k_a[A] + k_d = k_s$ and measuring k_s at different concentrations of A, the association rate constant can be obtained from the slope of the plot of k_s versus [A]. The results indicated that the introduction of a single mismatch at the center of 15-mer PNA–DNA and PNA–RNA duplexes gives rise to marked changes in the kinetics of both hybridization and dissociation.[60]

It is also possible to use a plain gold surface (e.g. BIAcore sensor chip J1) to immobilize PNA molecules

Figure 7 Typical response features (“sensorgram”) as measured by the BIAcore technique. The figure illustrates binding of an analyte to the sensor chip surface. The dissociation phase is generally followed by regeneration of the sensor chip surface.

carrying cysteine at the N-terminal side (Nordén and coworkers unpublished observations). The strong coupling between gold and sulfur was employed to immobilize the PNA molecule. This gives a better control over the surface coverage of the ligand and erroneous results due to nonspecific binding of ligands to the dextran layer can be eliminated. It is important to note that DNA has a very high affinity for gold and can be nonspecifically adsorbed on the surface without much effort. Direct addition of analyte DNA molecules to the sensor surface, to study its binding with PNA, might facilitate its adsorption to the gold surface. It is important to use short spacer molecules, e.g. mercaptohexanol, together with the ligand (probe) to form the PNA monolayer at the top of the sensor (gold) surface and prevent DNA molecules from being nonspecifically adsorbed to the surface.

3.3.3.2 Potentiometric Measurements Wang et al.[16] have reported the use of PNA as a recognition probe for the electrochemical detection of the hybridization event employing chronopotentiometric measurements. The method consisted of four steps: probe (PNA) immobilization on to the transducer surface, hybridization, indicator binding and chronopotentiometric transduction. The carbon paste electrode used in this process contained the immobilized DNA or PNA probe. The hybridization experiment was carried out by immersing the electrode in the stirred buffer solution containing a desired target. The strong adsorptive accumulation of the PNA was exploited for preparing the PNA modified surfaces and this adsorptive immobilization of short PNA oligomers leads to very effective hybridization biosensors. The potentials were sampled at a particular frequency and the derivative signal was recorded against the potential. The sensor was challenged with various noncomplementary oligomers and chromosomal DNA, including a 15-mer oligonucleotide containing a single-base mismatch. However, their results suggest that, in mixtures with the complementary strand, the noncomplementary oligomers have a profound effect upon the target signal at the DNA biosensor and a negligible effect upon that observed at the PNA-coated electrode.

3.3.3.3 Single-base Mismatch Analysis Using Quartz Crystal Microbalance Traditionally, the quartz crystal microbalance (QCM) has been used to monitor mass or thickness of thin films deposited on surfaces and to study gas adsorption and deposition on surfaces in the monolayer and submonolayer regimes.[61] The method has also been developed to use in liquid to apply it to the research areas related to electrochemistry or studying protein adsorption. The QCM is a very sensitive mass-measuring device. The resonant frequency of the crystal changes as a result of a minute weight increase on the surface. The

typical measurements include monitoring the shift in resonant frequency of the QCM due to mass changes. The technique also offers the possibility of obtaining additional information related to the dissipation factor, D, of the oscillator (the damping). Dissipation arises mainly owing to the internal friction and viscoelastic properties of the fluid. Recently, the method has developed further for use in liquids and simple techniques have been developed to measure dynamically changes in the dissipation of energy by the QCM operating in a liquid, e.g. due to adsorption on an electrode. Okahata et al.[62] reported the quantitative detection of M13 viral DNA containing a 10-base insert by hybridization to a complementary, 5′-thiol-modified, 10-base DNA probe adsorbed on a QCM. There are reports concerning the use of QCM to study sequence-specific binding of GCN4-bZIP peptides to immobilized DNA strands[63] and direct monitoring of DNA polymerase reactions on a QCM.[64] It is obvious that in situ detection of a hybridization event is possible by using QCM transducers and the method of detection is not related to the need of using an optical or redox indicator.

Since PNA hybridizes to complementary DNA strands with high affinity and sequence specificity, one might expect that immobilized PNA strands (or probes) would show an improved distinction between the closely related target sequences compared with an immobilized DNA probe. Wang et al.[65] reported a QCM biosensor based on peptide nucleic acid probes. The PNA probes, which formed the monolayer on the gold QCM surface, contained a cysteine attached to the PNA core with the help of an ethylene glycol unit. Immobilized PNA, in such a system, is capable of differentiating between a fully complementary and single mismatch oligonucleotide and a rapid detection of mismatch sequences is possible by monitoring the frequency–time response of the PNA–QCM biosensor upon addition of fully complementary and mismatch sequences. The remarkable specificity of the immobilized probe provides rapid hybridization and allows the use of low ionic strength solutions of short probes. Such a mismatch sensitivity of PNA immobilized QCM biosensors could be of great importance for diagnostic applications, particularly for genetic screening, and therapy.

4 SPECTROSCOPIC AND CRYSTALLOGRAPHIC METHODS

In this section we discuss briefly the applications of various spectroscopic methods to characterize the properties of PNA and the PNA–DNA complexes. We also discuss crystallography and its application to determining the structure of PNA and, finally, different computational techniques in connection with PNA applications.

4.1 Electronic Spectroscopy

In this section we consider different aspects of PNA applications related to ultraviolet/visible (UV/VIS) absorption spectroscopy and dichroic measurements.

4.1.1 Ultraviolet and Visible Absorption Spectroscopy

The UV absorption spectra of aqueous solutions of nucleic acids have been known since 1960. The absorption spectrum for polymeric nucleic acid(s) has been well characterized and is known to exhibit a characteristic maximum at 260 nm, a minimum around 230 nm and a second maximum below 200 nm.[66,67] Perhaps the simplest application of absorption spectroscopy to PNA is related to its concentration determination. In general, the relative mean molecular mass of a nucleotide is taken as 330 and the molar absorptivity of natural native double stranded DNA is considered as $\varepsilon_{260} = 6600\,\mathrm{M^{-1}\,cm^{-1}}$. In general, an aborbance at 260 nm (A_{260}) of 1.0 in a 1-cm cell corresponds to a DNA concentration of $50\,\mu\mathrm{g\,mL^{-1}}$. Molar absorptivities of single-strand DNA oligomers have been calculated from the base composition as a sum of the absorptivities of DNA monomers (mononucleotides) using Equation (4):

$$\varepsilon_{260} = 15.3n_{\mathrm{A}} + 7.4n_{\mathrm{C}} + 11.7n_{\mathrm{G}} + 9.3n_{\mathrm{T}} (\times 10^3\,\mathrm{M^{-1}\,cm^{-1}}) \tag{4}$$

where n_i denotes the number of bases of type I.[68–70] This equation has also been refined for a nearest neighbor model and the sequence dependence of the absorptivity of a ssDNA can be calculated using Equation (5):

$$\varepsilon_{260} = \sum_{i=1}^{N-1} \varepsilon(\mathrm{B}_i\mathrm{pB}_{i+1}) - \sum_{i=2}^{N-1} \varepsilon(\mathrm{B}_i\mathrm{p}) \tag{5}$$

where N is the total number of bases and $\varepsilon(\mathrm{B}_i\mathrm{pB}_{i+1})$ and $\varepsilon(\mathrm{B}_i\mathrm{p})$ are the molar absorptivities ($\mathrm{M^{-1}\,cm^{-1}}$) of the dinucleoside phosphates and mononucleotides, respectively, counted from the 5′-end.[71] The end nucleotides are not included in the second summation. However, the molar absorptivities for PNA monomers are not as well established as they are for DNA or RNA monomers. It is too much of a simplification to assume that a PNA oligomer should have the same molar absorptivity as its DNA or RNA counterpart. Since the backbone is different for this synthetic mimic, it is obvious that it could make a different kind of perturbation of the π-system of the nucleobases. Also, different stacking of the bases could give rise to a different extent of hypochromocity. The latter can be minimized if the absorption measurement is carried out at a high temperature (>75–80 °C). Once the molar absorptivity of a PNA sequence has been calculated, the concentration of the stock solution can be

determined by measuring the absorbance of the sample at 260 nm following the Lambert–Beer law as Equation (6):

$$A_\lambda = \log\left(\frac{I}{I_0}\right) = \varepsilon c l \qquad (6)$$

where A_λ is the absorbance at wavelength λ, I_0 and I are the intensities of light before and after the sample, respectively, l is the pathlength of the cell and c is the concentration. Since the molar absorptivities of different PNA monomers are not well characterized and contributions of the peptide backbone to the perturbation in the π-system of the nucleobases are not known, for all practical purposes the concentration of a PNA oligomer is determined in the following way.[43] Concentration determination is based on the absorption at 260 nm and 80 °C. At this temperature, the nucleobases are considered completely destacked and the contribution from the backbone is assumed to be negligible. The absorptivity is considered as the sum of the absorptivities of DNA monomers and effective ε_{260} per single strand is calculated by using Equation (4). A value of 3000 M^{-1} cm^{-1} can also be used[46] for the PNA oligomers containing pseudoisocytosines (J bases).

Absorption spectroscopy is also important in PNA applications to monitor the hybridization of appropriate single strands to form the corresponding duplex, both pure and hybrid, structures. In general, solutions of single strands are heated to 80 °C followed by adjustment of concentration (~2–3 mM per strand) from absorption measurements and the respective single-strand solutions are allowed to mix at that temperature. This is followed by a slow cooling step to ensure proper annealing of the strands.

The thermal melting temperature, T_m, defined as the temperature at which 50% of the complexes have been dissociated, gives an idea of the stability of the PNA–PNA or PNA–DNA duplex. In principle, the thermal melting temperature (and also entropy and enthalpy) of a PNA duplex, pure and hybrid, is estimated by monitoring the change in absorption at 260 nm at different temperatures and the corresponding plot of A_{260} versus temperature gives the thermal melting profile of a PNA duplex. Absorption melting provides information about different structural transitions. However, sometimes some information related to structural transitions is invisible in absorption melting owing to some associated factors, e.g. self-stacking and self-melting. It is often possible to overcome this problem by studying the circular dichroism (CD) melting, which can also provide supplementary information to complement the absorption melting study. The properties of PNA–PNA and PNA–DNA duplexes have been extensively investigated by employing absorption spectroscopy. The PNA oligomer H-TGTACGTCACAACTA-NH_2 forms an antiparallel duplex with complementary DNA with a T_m value of 70 °C. The corresponding DNA–DNA complex has a T_m of only 53 °C. However, the corresponding parallel duplex shows a transition temperature of 56 °C.[4] The thermal stability of PNA–RNA duplexes is higher than that for PNA–DNA duplexes.[60] The increased thermal stability of PNA–PNA duplexes relative to the corresponding DNA–DNA duplexes is fundamentally due to the absence of any significant electrostatic repulsion between the two strands in the former.

The stability of PNA–DNA hybrids is not very much affected by changes in ionic strength, except in the limit of low ionic strength where the stability increases. Owing to the higher sequence specificity of PNA upon binding to nucleic acids, incorporation of any mismatch in the duplex considerably affects the thermal melting temperature of the heteroduplex. For the heteroduplex corresponding to the PNA sequence H-egl-GGCAGTGCCTCACAA-NH_2 (C-terminal), and its full complementary DNA 5′-TTGTGAGGCACTGCC-3′, a mismatched incorporation of A in the eighth position of the DNA sequence, in place of G, reduces the T_m from 72.3 to 58.1 °C (Table 2) (Nordén and co-workers unpublished observations).

Homopyrimidine PNAs binds complementary DNA sequences to form $(PNA)_2$–DNA triplexes, and well-defined melting curves are obtained for these structures. The stability of the complexes depends on the length of

Table 2 Thermal stabilities of PNA–DNA duplexes

PNA sequence	DNA sequence	Melting temperature (°C)
H-egl-GGCAGTGCCTCACAA-NH_2[a]	5′-TTGTGAGGCACTGCC-3′[b]	72.3
	5′-TTGTGAG**A**CACTGCC-3′	58.1
	5′-TTGTGAG**A**CA**T**TGCC-3′	39.0
H-egl-GGCAGCGCCTCACAA-NH_2	5′-TTGTGAGGCGCTGCC-3′	>85
	5′-TTGTGAGGC**A**CTGCC-3′	69.9

[a] Self-melting of this PNA sequence is 44.7 °C.
[b] The thermal melting temperature of the full complementary DNA duplex (5′-TTGTGAGGCACTGCC-3′ and its complementary sequence) is 42.2 °C.

the oligomers in a regular manner with an increase in T_m of approximately 10 °C per base pair. For identical decamer sequences (antiparallel duplex), the T_m corresponding to PNA–PNA, PNA–DNA and DNA–DNA sequences are 67, 51 and 33.5 °C, respectively. However, the parallel PNA–PNA complex ($T_m = 47$ °C) is still considerably more stable than the corresponding parallel DNA–DNA duplex.[72]

4.1.2 Circular Dichroism and Linear Dichroism

CD and LD spectroscopic techniques early unveiled important structural aspects of PNA and PNA–nucleic acid hybrids.

4.1.2.1 Circular Dichroism CD is the differential absorption of left and right circularly polarized light ($CD = A_l - A_r$). Chiral molecules, i.e. molecules having nonsuperimposable mirror images, exhibit characteristic optical activity, i.e. they induce a rotation of the plane polarized light, and show an intrinsic CD. An achiral molecule has an identical mirror image and it does not show any CD. However, if an achiral molecule interacts with a chiral environment, the former may gain some optical activity through coupling of the two systems and may, in turn, show an induced CD. When a supermolecular structure includes a set of chromophores, assembled into a helical structure, the coupling between transitions may also generate a considerable amount of CD signal. The CD spectrum of a particular molecule is very sensitive to changes in the secondary structure and is useful for the detection of conformational changes of the molecule, e.g. the secondary structure of DNA and protein.

Since PNA contains an achiral backbone, it does not show any CD spectrum. However, certain modifications on the backbone structure and its conjugation with complementary DNA and RNA sequences to form hybrids render the potential for using it as a probe in CD studies (Figure 8a–c). A PNA duplex containing L-lysinylamide attached to the carboxy terminus of the PNAs demonstrates handedness resulting from the helicity of the structure. The source of CD can be attributed to the chiral orientation of the base pairs relative to each other. It has been demonstrated that the induced helicity, as measured by CD, is dependent on the nucleobase sequence proximal center.[73] CD spectroscopy of PNA–DNA and PNA–RNA duplexes provided the first information about the overall base-pair geometry in these complexes. The CD spectra of DNA–DNA and antiparallel PNA–DNA and PNA–RNA duplexes are similar, suggesting that PNA participates in the formation of right-handed helices with a base-pair geometry not much different from that found in a B- or an A-form DNA helix. In contrast, the spectra of parallel PNA–DNA and PNA–RNA duplexes deviate more from the DNA–DNA spectrum, suggesting a different kind of base stacking. CD spectroscopy was also early used to prove the formation of a right-handed PNA–DNA triplex structure.[34] Another important application of CD in this area is the study of the binding of different nucleic acid binding ligands

Figure 8 CD spectra of GTAGATCACT.AGTGATCTAC duplexes: (a) PNA–PNA with terminal L-lysine (curve 1) and D-lysine (curve 2) residue. (b) Antiparallel PNA–RNA (curve 1) and PNA–DNA (curve 2) duplexes, and parallel PNA–DNA (curve 3) duplex. (c) DNA–DNA (curve 1) and PNA–PNA (curve 2) duplexes. (Figure adapted by permission from Dr Pernilla Wittung.)

to PNA–DNA duplexes. It has been concluded that incorporation of a PNA strand/strands drastically reduces the binding capability of both minor groove binders and intercalators.[74]

4.1.2.2 Linear Dichroism LD is defined as the anisotropic absorption of linearly polarized light. LD depends mainly upon a vectorial quantity termed the ''transition moment'', which corresponds to one particular direction in each molecule.[75] Light polarized parallel to the transition moment has maximum probability of absorption, whereas if the polarization of the light is perpendicular to the transition moment, no absorption can take place. For solutions of macromolecules, such as DNA and other polyelectrolytes, flow fields or electric fields have been used for orienting the sample molecules. For a flow orientation experiment LD can be written as Equation (7):

$$\mathrm{LD}(\lambda) = A_{\parallel} - A_{\perp} \tag{7}$$

where $A_{\parallel}$ and $A_{\perp}$ are absorption of linearly polarized light in the parallel and perpendicular direction, respectively, with respect to the flow direction. A dimensionless quantity, often used in LD study, (LD^{r}) or reduced linear dichroism, is defined by Equation (8):

$$\mathrm{LD}^{\mathrm{r}}(\lambda) = \frac{\mathrm{LD}(\lambda)}{A_{\mathrm{iso}}(\lambda)} \tag{8}$$

where $A_{\mathrm{iso}}(\lambda)$ is obtained from the absorption spectrum of the isotropic sample, that is, in the absence of flow. LD^{r} is related to the orientation of the light-absorbing transition moments according to Equation (9):

$$\mathrm{LD}^{\mathrm{r}}(\lambda) = SO(\lambda) = \frac{3}{2} S \sum F_{\mathrm{I}}(3\cos^2\alpha_{\mathrm{I}} - 1) \tag{9}$$

where S is an orientation factor $0 \leq S \leq 1$ describing the degree of orientation of the principal axis, i.e. the helix axis in the case of DNA, relative to the flow direction, $O(\lambda)$ is an optical factor defined by the second sign of equality in the above equation, and is given by the angles α_{I} between the helix axis, as in case of DNA, and the transition moments responsible for the absorption of light, and the weight factors $F_i = \varepsilon(\lambda)_i/\quad \varepsilon(\lambda)_{\mathrm{I}}$ defining their respective contributions to the absorption at the particular wavelength λ. In principle, the π–π^* transitions of the DNA bases are responsible for the LD of polydeoxynucleotides around 260 nm and are polarized at various angles in the plane of the bases. If we consider that base planes are perfectly perpendicular to the helix axis of the DNA, the angle α_{I} would all be equal to 90° for the π–π^* transitions so that $O(\lambda) = -1.5$ and $\mathrm{LD}^{\mathrm{r}}(\lambda)$ becomes constant and independent of wavelength. In practice, the bases are generally somewhat inclined from perpendicularity and a certain wavelength dependence of the optical factor $O(\lambda)$ and of $\mathrm{LD}^{\mathrm{r}}(\lambda)$ can be anticipated.

From the measurements of LD it was shown early that PNA-T_8 forms a right-handed PNA_2–DNA triple helix with poly(dA) in which the base triplets are arranged with their planes approximately perpendicular to the helix axis, virtually similar to standard poly(dA)–$(\mathrm{poly(dT)})_2$ triplex. This PNA_2–DNA triplex structure is remarkably rigid, which indicates an efficient stacking interaction. The single-stranded DNA, owing to its high flexibility, cannot display any measurable (appreciable) LD signal under the influence of shear flow. If the PNA is added to this at a 2:1 (T:A) stoichiometry the LD signal shows a drastic increment around the 260-nm region. This indicates that the stiffness of the PNA–DNA triplex arises from base–base contacts, which prevent the bending of the chain. Also, the strong negative LD^{r} spectrum of the poly(dA)[PNA-T_8] triplex in the region 230–290 nm is more or less similar to that of the corresponding DNA triplex.[76] It was concluded from the above study that the base tilts in the two cases were similar to each other.

Interestingly, based on the LD measurements,[76] it was also concluded that no duplex stretches are present at subsaturation ratios but that segments of PNA_2–DNA triplexes are distributed evenly on the poly(dA) strand separated by flexible single-stranded regions. Only close to the saturation point, 2:1 PNA to DNA bases, does the complex become rigid owing to complete coverage by triplex and stacking between each PNA triplex segment. CD also indicated a complete absence of duplex at all mixing ratios.

4.2 Vibrational Spectroscopy

Vibrational spectroscopy is another important spectroscopic method which has been used to study biomolecules for many years. Vibrational spectroscopic studies include infrared (IR), infrared linear dichroism (IRLD) and Raman spectroscopy and, more recently, Raman optical activity (ROA). These techniques are capable of providing important structural information. So far, there has been no representative report related to vibrational spectroscopic studies regarding PNA applications. However, we believe that this particular area of spectroscopy is capable of providing new information related to peptide nucleic acid structure and function. Here, we discuss briefly how these different methods are applied to the study of nucleic acids and try to highlight how they can be made useful for PNA applications.

4.2.1 Infrared Spectroscopy

The IR spectrum of different forms of the same polynucleotides (DNA) shows large differences in vibrational

frequencies and intensities.[77,78] The whole spectrum of DNA covers the range 1800–700 cm^{-1}, which also includes vibrations involving the phosphate groups located around 1230 and 1090 cm^{-1}. However, for the bases, double-bond in-plane vibrations, in-plane ring vibrations and out-of plane ring bending vibrations are found in the regions 1800–1500, 1500–1100 and below 800 cm^{-1}, respectively. It is also known that bases contribute to the IR spectra of nucleic acids differentially and any structural transition is accompanied by a shift in the spectrum. This technique, particularly the most frequently employed Fourier transform infrared (FTIR) method, can be used for conformational studies of different PNA duplexes, pure, hybrid or chimeric. Moreover, a comparison with the corresponding DNA structure will be helpful in delineating the structure. Contributions from a different backbone will also be helpful in finding information regarding the influence of backbone structure in nucleic acid hybridization and of intermolecular interactions.

4.2.2 Infrared Linear Dichroism

This technique is capable of providing additional structural data regarding oriented samples. For nucleic acid studies, samples are generally oriented by depositing a droplet of a concentrated solution on an IR-transparent support and by stroking the drying sample unidirectionally, or by applying a wet spinning method utilizing a simultaneous precipitation and stretching of DNA fibers. In IRLD measurements, two IR spectra are recorded with the electric field of the incident light directed parallel and perpendicular to the orientation axis of the polynucleotide. The conformational transition related to the formation of PNA–PNA or PNA–DNA duplex and PNA–PNA–PNA or PNA–PNA–DNA triplex can be studied in this way.

4.2.3 Infrared Vibrational Circular Dichroism

Infrared vibrational circular dichroism (IRVCD) appears to have certain advantages over conventional CD for gaining structural information related to nucleic acids. The IRVCD spectrum can be interpreted in terms of the relative position of the carbonyl groups of the nucleic acid bases and information on base alignment can also be achieved. This technique, if applied to study different complexes of PNA, particularly those containing terminal lysinyl residues, might provide valuable information related to the structure and to study certain transitions which are otherwise invisible in electronic CD. IRVCD requires very high concentrations of sample (20–30 mg mL^{-1}), a major disadvantage of this application.

4.2.4 Raman Spectroscopy

Raman spectroscopy is also a powerful spectroscopic method suitable for use in the conformational study of nucleic acids.[79] The major advantage of this technique over conventional IR spectroscopy is the possibility of carrying out measurements in aqueous solutions. The Raman spectrum of nucleic acids is obtained within the range 600–1800 cm^{-1} and, in general, reflects the same vibrational states of various bonds associated with the conventional IR spectrum. Raman spectra can also be used to detect small (local) conformational changes associated with intermolecular interactions, particularly near the binding sites, using small model systems.

4.2.5 Resonance Raman Spectroscopy

Conformational changes in nucleic acids can also be studied using resonance Raman spectroscopy, where excitation in the wavelength range of the electronic absorption of nucleic acid bases is used. A concentration range about 20–100 times lower than in conventional Raman spectroscopy can be used for this kind of study. This method should be suitable for PNA applications, especially to gain information about conformational changes of the bases. Also, structural information related to pure, hybrid or chimeric duplexes or triplex structure of PNAs might be compared with corresponding pure deoxyriboucleotide or ribonucleotide structures to obtain an insight into the influence of the backbone on the individual conformation.

4.3 Nuclear Magnetic Resonance Spectroscopy and Mass Spectrometry

In this section we briefly discuss PNA applications of nuclear magnetic resonance (NMR) spectroscopic and mass spectrometric techniques. In mass spectrometry we mainly focus on the use of MALDI/TOFMS to characterize PNA and analyze genetic mutation.

4.3.1 Nuclear Magnetic Resonance Spectroscopy

NMR spectroscopy is probably the most powerful tool to analyze in detail the conformation of oligonucleotides in solution. ^{31}P-NMR has been widely used to elucidate phosphodiester bond conformation. In proton NMR, in most cases, the two-dimensional nuclear Overhauser effect[80] has been used to characterize the interproton distances of different parts of the nucleic acid molecule. Consequently, characterizations of different kinds of nucleic acid structures have been carried out. The majority of the work concerning the conformation of various DNA sequences has been done on synthetic oligonucleotides, as high-molecular-weight samples give broad peaks and less good resolution.

NMR spectroscopy has also been successfully applied to determine solution structures of different oligomers, pure and hybrid, of PNA. The monomer exists as both the *cis* and *trans* rotamers about the tertiary amide bond, slightly favoring the *trans* conformation[20] as revealed from the ^{1}H spectra. The two rotamers interconvert on the timescale of ~1 s at room temperature. For longer sequences, as determined from the ^{1}H-NMR spectrum of the PNA strand H-GCTATGTC-NH_2, a multitude of structural species can exist. If n is the total number of residues, then the possible number of structural species will be 2^n.

The solution structures of antiparallel PNA–DNA (H-GCTATGTC-NH_2-5′d[GACATCGC]) and PNA–RNA (GAACTC-5′r[GAGUUC]) duplexes have been determined by ^{1}H-NMR.[20,81–83] The PNA–DNA duplex shows a helical conformation with Watson–Crick base pairing scheme. The major groove is wide and deep while the minor groove is narrow and shallow. The helical rise is about 42 Å with approximately 13 base pairs per turn and the helical diameter is close to 23 Å. The carbonyl groups on the backbone base linkers of this structures are oriented along the backbone, pointing in the C-terminal direction. However, the sugar puckering is predominantly in the C2′-endo conformation with all *anti*-glycosidic torsion angles and *trans* primary amide bond conformations. The PNA–RNA duplex molecule has features similar to a right-handed A-helix. The carbonyl groups of the PNA backbone linkers are directed towards the C-terminus and primary amide bonds are also in a *trans* conformation. The nucleic acid strand possesses features very similar to an A-type structure, with C3′-endo sugar pucker and glycosidic torsion angles near -160°.

The structural properties of complexes of PNA are of great interest. However, the information available regarding the structural details has so far been rather limited.

4.3.2 Mass Spectrometry

Mass spectrometers measure the mass-to-charge ratios (m/z) of gas-phase ions. The gas phase is created by different ionization methods, e.g. electron ionization, chemical ionization, fast atom bombardment, electrospray ionization and matrix-assisted laser desorption ionization (MALDI). Mass spectrometry has become an increasingly important tool for the accurate, efficient and fast routine analysis of nucleic acids. It can instantly separate and detect DNA fragments on the basis of their mass-to-charge ratio and, thereby, can allow the determination of DNA length. The MALDI method is a comparatively new method and undoubtedly suitable for high-molecular-weight compounds such as proteins, peptides, DNA/RNA or PNA oligomers. A MALDI spectrum consists of singly charged quasimolecular ions, e.g. $[M + H]^+$, $[M + Na]^+$, $[M + K]^+$, for each sample component. The sample is mixed with a suitable MALDI matrix such as sinapinic acid in a ratio of 1 : 100. This is allowed to dry on a metal surface. A laser beam is then directed at this surface, causing desorption and ionization of sample components. The development of the MALDI method coupled with time-of-flight (TOF) mass spectrometry has provided an alternative approach to the analysis of nucleic acids.[84,85] It has also been successfully employed to study different PNA applications, particularly the characterization of PNA and genetic analysis.

It has been shown that typical matrices, e.g. sinapinic acid, useful for protein study are also suitable for use in PNA studies. PNAs survive the MALDI process intact and are easily ionized. The method holds potential for a rapid evaluation of the purity of a newly synthesized PNA oligomer and provides valuable sequence information regarding the synthesis by-products. It has also been found that dsPNA does not survive the MALDI process under certain experimental conditions.[29]

MALDI/TOFMS has also been successfully used to study discrimination of single-nucleotide polymorphisms (SNPs) in human DNA using PNA probes.[30] Human genomic and mitochondrial DNA contain a large number of SNPs that are linked to diseases. Rapid and accurate screening of important SNPs, based on high-affinity binding of PNA probes to DNA, is possible by using MALDI/TOFMS. The captured single-stranded DNA molecules are first prepared by PCR amplification and thereafter hybridized with PNA probes in an allele-specific fashion. MALDI/TOFMS is then used for the rapid and precise detection and identification of the hybridized PNA probes. This provides a very straightforward, rapid, accurate and specific detection of SNPs in amplified DNA. Another powerful feature of this approach is that the direct analysis is made in seconds.[30,86] Griffin et al.[87] reported an approach for the detection of multiple point mutations, using allele-specific, mass-labeled PNA hybridization probes following a direct analysis using MALDI/TOFMS. The resultant mass spectra depict peaks of distinct masses corresponding to each allele present. A mass spectral ''fingerprint'' of each DNA sample is obtained.

4.4 Crystallography and Its Applications

In this section we discuss crystallography and its application in determining the structure of PNA. We also include a few comments in connection with computational studies in PNA structures.

4.4.1 Structure of PNA

The crystal structure of a PNA duplex (H-CGTACG-$NH_2)_2$ obtained at 1.7 Å resolution and crystallized in space group $P_{1\ bar}$ shows both a right- and a left-handed helix in the unit cell.[88] The helical parameters estimated from this study reveal that the helix is wide (28 Å) and the pitch is large (18 bp) compared with the conventional A- or B-form. The twist, rise, base tilt and displacement values are 19.8, 3.2, 1.0 and 8.3 Å, respectively. One helical turn of PNA duplex is 58 Å long. However, the most important conclusion drawn from the results of the crystallographic study of Nielsen et al.[20,88] is that they confirm the discovery by Wittung et al.[72,73] of a PNA–PNA double helix, showing that a sugar phosphate backbone is not a prerequisite for the formation of a nucleobase double helix.

The crystal structure of the PNA_2–DNA triplex shows considerable deviations from those of nucleic acid triplexes.[89] The purine DNA strand undergoes a Watson–Crick base pairing with the homopyrimidine PNA strand in an antiparallel orientation and forms Hoogsteen hydrogen bonds to the second PNA strand of identical sequence running parallel with the DNA. The two PNA strands in the triplex structure resemble the PNA strand in the PNA–DNA duplex. The PNA_2–DNA triplex is wide (diameter $\sim$ 26 Å) and the pitch is approximately 16 (triplet). The sugar puckering in the DNA strand is C3′-endo and the backbone torsional angles are similar to those of an A-form structure. The structure is further stabilized through a network of water molecules specifically bound in the minor groove.

4.4.2 Computational Techniques

Molecular modeling and dynamics studies of nucleic acid duplex and triplex structures have complemented the structural information available from NMR and X-ray studies. They have provided potentially useful insights into the three-dimensional conformations of double and triple helical structures. Recent improvements in force field parametrizations and molecular dynamics (MD) algorithms have made a more accurate modeling of nucleic acid (and its mimic) structures possible. With the availability of NMR and X-ray data[20,81–83,88,89] regarding homo- and hetero-duplex and triplex structures, researchers have been taking interest in different computational studies of PNAs. Sen and Nilsson[90] reported molecular modeling and dynamics simulation studies on homo- and hetero-duplexes of PNA in aqueous solution under periodic boundary conditions and their results show very good agreement with the respective NMR and X-ray crystallographic data. A MD simulation study of a PNA·DNA–PNA triplex helix in aqueous solution by Shields et al.[91] gave a certain insight into the conformational flexibility of the structure. It was concluded from energetic analysis that the hybrid PNA–DNA triplex has helical characteristics which are different from those of its actual DNA counterpart. The reason is not simply the replacement of sugar–phosphate by PNA backbones. The definite conformational preferences of the PNA strands influence the driving force behind this conformational flexibility. Srinivasan and Olson[92] reported a molecular modeling study involving a PNA·DNA–PNA triplex. A total of 12 acyclic torsion angles determine the conformation of adjacent bases in PNA versus nine variables, including the sugar ring, in DNA. Moreover, it was also concluded that the replacement of the sugar ring by a linear bond sequence introduces torsional freedom not present in the nucleic acid. The 12 torsional angles are divided into two groups. The first group, the independent variables, includes torsional angles analogous to the glycosyl and ring torsions of the nucleic acids. The second or the dependent set arises in the successful closure of the PNA backbone.[92] The information available from these modeling studies, based on predicted structures and cross-examined in terms of the current spectroscopic, calorimetric and crystallographic data, explains why PNA cannot form a very B-like structure.

5 CONCLUSIONS

PNA is a very attractive lead compound owing to its considerable chemical and biological stability and its very specific interactions with DNA and RNA. The application of PNA as a genetic therapeutic agent has to await the development of efficient and safe methods for its cell penetration. However, its application as a recognition molecule has led to promising developments in many areas of chemistry, biology and biotechnology.[93,94] Continuing efforts in this area of research may yield novel base analogs[39,95–98] and provide further applications of this most exciting nucleic acid analog.

ABBREVIATIONS AND ACRONYMS

BIA	Biomolecular Interaction Analysis
CD	Circular Dichroism
CE	Capillary Electrophoresis
CFTR	Cystic Fibrosis Transmembrane Conductance Regulator Gene
CGE	Capillary Gel Electrophoresis
FTIR	Fourier Transform Infrared

HPLC	High-performance Liquid Chromatography
IR	Infrared
IRLD	Infrared Linear Dichroism
IRVCD	Infrared Vibrational Circular Dichroism
LD	Linear Dichroism
LD^r	Reduced Linear Dichroism
LIF	Laser-induced Fluorescence
MALDI	Matrix-assisted Laser Desorption Ionization
MALDI/TOFMS	Matrix-assisted Laser Desorption Ionization/Time-of-Flight Mass Spectrometry
MD	Molecular Dynamics
NMR	Nuclear Magnetic Resonance
PARC	PNA-assisted Rare Cleavage
PBG	Poly-γ-benzylglutamate
PCR	Polymerase Chain Reaction
QCM	Quartz Crystal Microbalance
ROA	Raman Optical Activity
SNPs	Single-nucleotide Polymorphisms
SPR	Surface Plasmon Resonance
TOF	Time-of-flight
UV	Ultraviolet
UV/VIS	Ultraviolet/Visible
VNTR	Variable Number of Tandem Repeat
5′-UTR	5′-Untranslated Region

Polycyclic aromatic compounds (PACs) induce tumors by reacting with specific sequences of the initiating oncogene. The resulting DNA damage is converted into oncogenic mutation by in situ mutagenesis during repair or replication. The analysis of PAC/DNA reaction specificity is crucial for understanding the molecular biology of tumor initiation.

The sequence specificity of PAC/DNA reactions has been analyzed by various methods. These methods detect different types of DNA-damage lesions. For example, alkali-labile lesions can be mapped by a chemical procedure (piperidine treatment) and bulky stable adducts can be mapped by a photochemical method (laser-induced strand scission). Biochemical studies have identified several enzymes that act on damaged DNA and can be used for mapping the location of PAC/DNA reactions. For example, DNA lesions block the processive bypass of various enzymes (DNA polymerases, RNA polymerases and exonucleases), whereas some endonucleases (UvrABC exinuclease, S1 nuclease and apurinic/apyrimidinic (AP) endonuclease) make lesion-specific incisions. Therefore, the sites of PAC reactions with DNA are mapped by treating PAC-damaged DNA with these enzymes to generate lesion-specific DNA strand breaks that are resolved by denaturing polyacrylamide gel electrophoresis. More recently, various polymerase chain reactions (PCRs) have been developed for mapping the sequence preferences of PAC/DNA reactions in vivo. These techniques include ligation-mediated polymerase chain reactions (LMPCRs), single-strand ligation polymerase chain reactions (SSLPCRs) and terminal transferase-dependent polymerase chain reactions (TTDPCRs). In these methods, the PCR is used to amplify gene-specific DNA fragments generated by chemical or enzymatic DNA lesion processing.

1 INTRODUCTION

PACs, a group of potent environmental carcinogens found in organic combustion residues, are etiological agents of human skin and lung cancer.[1] These tumors often carry oncogenically mutated *ras* genes.[2] To facilitate the study of tumor formation by PACs, model mice suitable for carcinogenesis experiments have been developed.[3] A high number of the tumors that are induced by placing PACs on the backs of these mice are found to contain oncogenic H-*ras* mutations.[4,5]

Structure **(1)** is benzo[*a*]pyrene (BP); **(2)** is 7,12-dimethylbenz[*a*]anthracene (DMBA); and **(3)** is dibenzo-[*a*,*l*]pyrene (DB[*a*,*l*]P). All three are widely studied, potent PAC carcinogens. The tumor-forming potentials of PACs are determined by two types of experiments conducted in mouse skin: *initiation–promotion* and *repeated application*. In the initiation–promotion experiments, mice are treated once on the skin with a PAC (forming initiated cells) and then with multiple treatments with promoting agents, most commonly TPA (12-*O*-tetradecanoyl phorbol 13-acetate) to induce the initiated cells into forming tumors. This type of study determines the *tumor-initiating* potential of the PAC. In the repeated application experiments, mouse skin is repeatedly treated with a PAC. In these experiments, PACs act both as initiators and promoters. Tumors formed from this type of experiment reflect the *carcinogenic* potential of the PAC. Studies indicate that DB[*a*,*l*]P is the most potent carcinogen of all PACs tested so far.[6,7]

The reaction of PACs with biological macromolecules is necessary for cancer induction.[8] In their environmental forms, however, PACs do not react with biological macromolecules. PACs are oxidized in vivo by cytochrome P450-mediated pathways, a process that has been referred to as *metabolic activation*.[9] Two major pathways, commonly referred to as the *diol epoxide* pathway and the *radical cation* pathway, are involved in the metabolic activation.[9] A third possible pathway (quinone-forming) that may be active for some PACs (such as BP), has also been described.[10,11] Metabolic activation of the parental PAC generates electrophilic

derivatives[12] that react with DNA, RNA and proteins. Studies have established that PAC/DNA reactions are important in tumor initiation.[3,9]

Various in vitro and in vivo studies have been conducted to investigate the nature of PAC/DNA reactions. These studies indicate that PACs react preferentially with purine bases. PAC reactions with certain sites in DNA bases, such as the N^2- of the guanine (Gua) or N^6- of adenine (Ade), lead to the formation of bulky adducts that are chemically stable and have therefore been described as *stable adducts*. On the other hand, when PACs react at the N3- or N7- of Ade or at the N3-, N7- or C8- of Gua, the adducts undergo spontaneous hydrolysis of the bond between the purine base and deoxyribose, and have therefore been described as *depurinating adducts*. Both PAC-diol epoxides and PAC-radical cations can form stable and depurinating adducts (for a review, see Cavalieri and Rogan[9]).

The stable adducts and abasic sites formed by the depurinating adducts are pre-mutagenic lesions and are involved in tumor initiation. Table 1 shows a partial summary of our studies that suggest that depurinating adduct formation may be a common characteristic of some potent PAC carcinogens. Specifically, these studies indicate that, for these strong carcinogens, depurinating DNA adducts are stochastically related to the oncogenic, clonal H-*ras* mutations found in mouse skin tumors.[5]

Studies indicate that stable adducts are converted into tumor-initiating H-*ras* oncogenic mutations when cells carrying adducted chromosomes enter the S phase. At this time, replication bypass of adducted bases in the template strand induces base-incorporation errors.[14,15] Research in our laboratory suggests that PAC-induced abasic sites may be converted into mutations by repair errors.[13] Figure 1 shows the proposed misreplication and misrepair models.

PAC treatment on mouse skin often causes local inflammation. This can result in the induction of indirect oxidative DNA damage, including single- and double-strand breaks, formation of abasic sites, and oxidation of DNA bases. Thus, anti-oxidants were found to reduce tumor induction without interfering with stable adduct formation.[17] Research suggests that in PAC-treated mice, oxidative DNA damage (oxidized DNA bases in particular) leads to tumor promotion.[18] Further evidence for a promoting role was obtained from observations that oxidative DNA damage shortens the latency period between adduct formation and tumor appearance.[19]

Experiments to map PAC-reactive sequences in DNA, especially in the H-*ras* gene, can help in the understanding of various early events of tumor initiation. For example, the idea that mutagenesis occurs at the damaged bases in situ would be supported if PAC-reactive hotspot sequences were found to be mutated in preneoplastic tissue. Evidence suggests that stable adducts are

Table 1 PAC carcinogenicity, adduct formation in mouse skin and clonal H-*ras* mutations in papillomas

PAC	Relative carcinogenicity[a]	Adducts in mouse skin[a]		H-*ras* mutations[b]	
		Depurinating adducts	Stable adducts	Mutation	Mutation/tumor
DB[*a*,*l*]P	+++++	N7&N3Ade (81%) N7&C8Gua (18%)	N^6dA (0.44%) N^2dG (0.52%)	Codon 61 C<u>A</u>A ⟶ C<u>T</u>A	4/5
DMBA	++++	N7Ade (79%) N7Gua (20%)	Unidentified (0.9%)	Codon 61 C<u>A</u>A ⟶ C<u>T</u>A	4/4

[b] Data from Chakravarti et al.[5] and from unpublished observations. The oncogenically mutated H-*ras* gene was found to be present in 14–47% of the cells in papillomas.[13]

Figure 1 Proposed mechanisms for tumor-initiating mutagenesis from PAC-induced DNA damage. The misreplication model shows the formation of a GGC to GTC mutation at H-*ras* codon 13 from a benzo[*a*]pyrene-7,8-diol-9,10-epoxide (BPDE) stable adduct.[15] Two rounds of replication are necessary for generating the fixed (double-stranded) mutations. This pathway is thought to occur in replicating cells.[16] The misrepair model shows the formation of H-*ras* codon 61 CAA to CTA mutation from a DB[*a*,*l*]P depurinating adduct-induced abasic site through a single-strand mutation (a T · T mispair) intermediate.[13] The T · T heteroduplex is converted into a fixed mutation by one round of replication. This pathway may occur in resting cells. The fixed mutations are found in initiated cells.

repaired by nucleotide excision repair pathways in a sequence- and conformation-selective manner.[20,21] Mapping adduct sites at various times during DNA repair can help determine the effect of DNA sequence context and adduct conformation on the efficiency of repair. Some studies indicate that PAC-reactive hotspots (for example, benzo[*a*]pyrene-7,8-diol-9,10-epoxide (BPDE)-reactive gas chromatography (GC)-repeat sequences) frequently reside outside of oncogene-coding sequences, including the 5′-flanking sequences of H-*ras*.[22] The biological significance of such interactions is uncertain, but it is thought that the analysis of PAC interactions with non-coding sequences would be useful in antineoplastic drug design.[22] In this article we will review various approaches for mapping PAC/DNA reaction sites.

2 METHODS FOR MAPPING POLYCYCLIC AROMATIC COMPOUND – DNA REACTION SITES

2.1 Chemical Methods

The discovery that some of the BPDE-induced DNA damage is ''alkali-labile'',[23,24] led to the development of an approach to map the DNA sequence preference for the occurrence of these sites. Studies suggest that the alkali-labile sites may include at least two kinds of DNA damage. These include (a) the rapidly formed abasic sites from labile adducts and (b) the slowly hydrolyzing possible rearrangement derivative of N^2-Gua stable adducts.[24,25] Consequently, this approach has been a popular choice for PAC/DNA reaction site mapping. The alkali treatment often consists of heating PAC-reacted DNA with piperidine at 90 °C,[26–29] which results in DNA strand scission. The piperidine-induced strand scission reaction is an outgrowth of the Maxam–Gilbert sequencing methodology.[30] Investigation of N7-alkylguanines indicates that strand scission reaction occurs as the C8–N9 bond is ruptured and a formamido-pyrimidine structure is formed, which is displaced from the ribose moiety by piperidine.[31] The scission sites are electrophoretically analyzed in an appropriate denaturing polyacrylamide gel.

A majority of the mapping studies have been conducted with BPDE. In these experiments, linear DNA is radiolabeled at one end and reacted with the PAC and then treated with piperidine. These experiments indicate that PACs exhibit a specificity for three-nucleotide-long sequences. For example, Lobanenkov et al. reported that the central G of CGG, TGG, TGT and CGT is the preferred target for BPDE reaction.[27] Similar results have also been reported by other researchers, with Rill and Marsch reporting that the central G of AGG, CGG and TGN is the preferred target for

Figure 2 Piperidine mapping of "alkali-labile" sites induced by *anti*-BPDE and *anti*-DB[*a*,*l*]PDE in a segment of *p*BR322 DNA. DNA was linearized with *Nhe*I, and the 5′ end was dephosphorylated and then radiolabeled with T4 polynucleotide kinase and γ-^{32}P ATP. The resulting DNA was cleaved again with *Eco*RI and a 231 bp fragment gel purified to generate one-end-labeled linear DNA molecules. Then 25 ng of labeled DNA was reacted with 5 ng of a PAC diol epoxide in 30 µl reaction solutions containing 15% acetonitrile and 15% ethanol at room temperature in the dark for 3–20 min. Damaged DNA was extracted with chloroform/isoamyl alcohol, precipitated with ethanol and treated with 10% piperidine at 90 °C for 30 min. The fragmented DNA was resolved in an 8 M urea 6% polyacrylamide gel. A + G, Maxam–Gilbert sequencing ladder; no PAC, unadducted, piperidine-treated control.

BPDE reaction.[28] Using this technique, we have studied *anti*-BPDE- and *anti*-dibenzo[*a*,*l*]pyrene-9,10-diol-11,12-epoxide (*anti*-DB[*a*,*l*]PDE)-reactive sequences in a segment of an *Eco*RI-*Nhe*I fragment of *p*BR322 DNA[32] (Figure 2). In these experiments *anti*-BPDE was found to react with the central G of GGA sequences and both Gs of CGGC sequences. However, *anti*-DB[*a*,*l*]PDE showed comparatively weaker reactivity and no hotspots in these sequences. It is possible that *anti*-DB[*a*,*l*]PDE-induced DNA lesions are comparatively less alkali-labile.

It has been observed that BPDE lesions can be converted into strand breaks in the absence of alkali treatment, for example when DNA is incubated for extended periods at 37 °C.[26,27] Bigger et al. reported that when mapping BPDE- and benzo[*c*]phenanthrene diol epoxide-induced DNA damage, piperidine treatment could be replaced entirely by 24 h incubation at 37 °C.[29] These authors suggested that the strand breaks are formed by depurinating adduct-induced abasic site hydrolysis. However, BPDE induces a relatively small amount of depurinating adducts (1.2% N7Ade and 0.1% N7Gua) and a large amount of stable adducts (98% N^2Gua and 0.7% N^6Ade).[9] Since the BPDE-induced N7Gua depurinating adducts undergo rapid hydrolysis, the possibility that some of these strand breaks may have been induced by slow hydrolysis of stable adduct lesions cannot be ruled out. BPDE-induced strand nicking is also thought to occur from phosphate adducts.[33] We also observed that in this segment of DNA, the Gs in BPDE-reactive GGA sequences required piperidine treatment for strand breaking, whereas some of the BPDE-reactions with Gs in the CGGC sequences led to strand breaks without piperidine treatment (Figure 3). This suggests that the efficiency of DNA base loss could be determined either by the lability of particular adducts and/or by the sequence context of the adducted base.

Piperidine cleavage patterns may also help with the analysis of stable adduct-induced DNA ultrastructural changes. In these experiments, adducted DNA is first treated with a chemical probe for nucleic acid structure, such as diethyl pyrocarbonate (reacts with *syn*-purines in Z-DNA or single-stranded DNA), hydroxylamine (reacts with cytosine in single-stranded or distorted DNA),

Figure 3 Liability of sequence-specific BPDE-adduct damage. Mapping experiment conducted as described in Figure 3. No PIP, strand cleavage patterns without piperidine treatment; PIP, strand cleavage with piperidine.

chloroacetaldehyde and bromoacetaldehyde (reacts with A and C in denatured regions and B–Z interfaces) and osmium tetroxide (reacts with thymine residues in distorted DNA such as B–Z junctions).[34] Next, the phosphate sugar backbone is cleaved at the level of the adducted bases with piperidine and the resulting fragments are separated in a denaturing polyacrylamide gel. Using this strategy, Belguise–Valladier and Fuchs analyzed the conformational changes induced by covalently bound N^2-acetylaminofluorene (AAF) residues to Gua bases in oligonucleotides.[34] These experiments revealed that adduct-induced structural deformations extend over 4–6 bases centered around the adduct in both strands, but the nonadducted strand is more extensively distorted.

2.2 Photochemical Methods

BPDE-N^2Gua stable adducts distort DNA secondary structure.[35,36] Irradiation of the adduct complex with laser light at 355 nm results in a specific scission at the adducted base, which results in one single-strand DNA cut at each BPDE-bound base.[37] This method has been used to map the sites of BPDE-induced stable adduct formation. In this procedure, the adducted/irradiated DNA is resolved by denaturing polyacrylamide gel electrophoresis.[38,39] As can be expected from adduct analysis (98% of BPDE adduct is BPDE-N^2Gua), mapping results indicate that BPDE primarily forms adducts at G residues, but 5–10% of the strand scissions were found at A and C residues.[38] In general, these experiments indicated that G residues with adjacent G neighbors were preferred as targets over isolated G residues. However, a recent investigation with BPDE-adducted oligonucleotides indicates that a small but significant amount of photochemical strand scission also occurs at neighboring bases, up to 4 bases upstream and 7 bases downstream from the adducted base.[40] The bases in the complementary strand were also cleaved, but at 20-fold weaker frequency than the adducted strand.[40] Therefore, it is possible that some of the strand breaks in BPDE-induced, irradiated DNA could include such secondary targets.

The analysis of BPDE reactivity to H-*ras* DNA is of special interest, because of the expected role of site-specific DNA adduct formation in inducing tumor-initiating mutations. Analysis of human H-*ras* gene exon 1 and 2 sequences indicated that the central G residues of the two oncogenic sites in exon 1 (codons 12 (GGC) and 13 (GGT)) were approximately five times more reactive to BPDE than isolated G residues were.[39] BPDE did not show any reactivity towards the central A of oncogenic codon 61 (CAG) sequence in exon 2, but reacted with the G with moderate reactivity.[39] If all tumor-initiating mutations induced by BPDE are from stable adducts, these results would predict that BPDE-induced tumors would not contain H-*ras* codon 61 mutations.

2.3 Enzymatic Methods

2.3.1 Processive Enzymes

PAC-induced DNA lesions inhibit the bypass of several types of processive enzymes. These enzymes include DNA and RNA polymerases, and exonucleases. This property has been widely used to construct precision maps of the locations of base lesions in DNA.

2.3.1.1 DNA Polymerases Studies indicate that both stable adducts and abasic sites primarily terminate the processive synthesis of DNA polymerases. Bypass synthesis over stable adduct and abasic site lesions occurs relatively infrequently, and in a subfraction of these bypassed templates DNA synthesis is erroneous, incorporating noncomplementary bases.[41–43] Studies indicate that adduct-induced DNA chain termination is not due to a failure of the 3′–5′ (proofreading) exonuclease activity of DNA polymerases to remove a misincorporated base, but due to the failure of lesion bypass.[41] DNA synthesis chain terminations occur opposite the base 3′ to the stable adducted base[44] or abasic sites[45,46] on the template strand. T7 DNA polymerase has been a popular choice for mapping PAC-reactive sites.[47,48] In this procedure, often described as *primer extension* mapping, the primer is radiolabeled at the 5′ end and DNA synthesis is conducted on adducted DNA. Experiments indicate that BPDE reacts mainly with G residues (identified as a synthesis block one base prior to G at the template strand).[48] In the rat H-*ras* gene, BPDE was found to react with moderate specificity with the oncogenic central A of rat codon 61 (CAA).[47]

If the adducted DNA can be repeatedly used as a template for DNA synthesis, finer resolution maps will be possible. To take advantage of this possibility, a *linear amplification* protocol was developed with *Taq* DNA polymerase.[49] While trying to implement this protocol to map PAC/DNA reaction sites, we encountered the problem of a large background from prematurely terminated DNA synthesis. *Taq* DNA polymerase generates large amounts of incompletely synthesized DNA strands.[50] Premature chain termination, however, has not been reported to significantly affect the primer extension mapping procedure. Such premature chain termination is unlikely to be due to differences in DNA polymerase processivity.[51] Studies suggest that spontaneous misincorporation resulting in an unextendable 3′ base,[51] as well as other factors including the presence of stable secondary structures in duplex DNA that have been noted as ''pause'' sites for DNA polymerases, could be

involved.[52] Our studies indicated that efficient proofreading reduces premature chain termination.[51]

The following considerations were helpful in developing an efficient linear amplification protocol that allowed full-length chain extension. First, studies suggest that during DNA synthesis, a 5′ endonuclease activity associated with the 5′–3′ (nick-translating) exonuclease activity of some DNA polymerases helps them to overcome stable secondary structure barriers of strand synthesis.[53,54] Therefore, conducting DNA synthesis with enzymes that contain this activity may be beneficial for full-length chain extension. Second, it has been suggested that the polymerase activity contained in a DNA polymerase outcompetes other activities associated with the enzyme during DNA synthesis.[55] We found that when DNA synthesis was carried out with a nick-translating DNA polymerase supplemented with a small amount of proofreading DNA polymerase, the fidelity of DNA synthesis was greater than when the enzymes were acting singly.[13] This suggested that such an enzyme combination would provide an effective way of enhancing proofreading activity during DNA synthesis. Accordingly, by using a 8:1 mixture of *Tth* and *Vent* DNA polymerase, we were able to obtain optimal full-length single-strand DNA synthesis.[51] We employed this strategy to construct a linear amplification map of *anti*-BPDE-, *syn*- and *anti*-DB[*a*,*l*]PDE-reactive sequences in the mouse H-*ras* exon 2 region. In these experiments, linearized target DNA is linearly amplified with a single 5′-end radiolabeled primer and the reaction products are analyzed in a denaturing polyacrylamide gel. The results indicate that the central A of codon 61 (CAA) reacts with these PACs with moderate specificity (*anti*-BPDE) and average reactivity (*syn*- and *anti*-DB[*a*,*l*]PDE) (Figure 4).[51]

2.3.1.2 RNA Polymerases RNA synthesis by DNA-dependent RNA polymerases is also terminated by DNA adduct lesions. Studies indicate that, like DNA polymerases, T7 RNA polymerase can also occasionally bypass DNA lesions and incorporate noncomplementary bases. One study suggests that when T7 RNA polymerase inserts an incorrect base across the BPDE–N^2-Gua adduct it leads to premature chain termination, and such a mechanism may contribute to the fidelity of transcription-coupled nucleotide excision repair.[56] Another study, however, suggests that T7 RNA polymerase can bypass BPDE-N^6Ade adducts with high efficiency and generate full-length runoff transcripts.[57] Eukaryotic RNA polymerase III is less able to bypass lesions than T7 RNA polymerase.[58] The presence of adducts in the template strand is expected, and they are found to be potent terminators of RNA chain growth. It was found that the presence of adducts in the displaced strand could slow down but not terminate RNA chain synthesis by T7 RNA polymerase.[59]

RNA polymerases have been used to map sites of DNA adduction. In these experiments the target DNA is positioned downstream from a suitable promoter sequence, is treated with PAC from adducts, and *runoff transcription* reactions are conducted with an appropriate RNA polymerase. T7 RNA polymerase[59–62] and SP6 RNA polymerase[48] have been commonly used in these studies.

Essentially similar results have been obtained from BPDE-induced DNA damage mapping experiments conducted either with primer extension reactions with DNA polymerase or runoff transcription reactions with RNA polymerase. For example, BPDE was found to react with G residues in GC boxes.[60] Since DNA and RNA fragments move differently in sequencing gels, it is difficult to compare the two types of mapping. Nevertheless, Thrall et al. were able to compare BPDE-reactive maps constructed by primer extension by T7 DNA polymerase and by runoff transcription by SP6 RNA polymerase.[48] From these studies they concluded that modified bases that pose relatively strong blocks to DNA polymerase do not always pose a similarly strong block for RNA polymerase. In addition, since different stable adducts were found to block T7 RNA polymerase differently,[56,57] runoff transcription experiments may yield poor resolution maps compared with DNA polymerase.

2.3.1.3 T4 Exonuclease (3′-Exonuclease Activity of T4 DNA Polymerase) T4 DNA polymerase contains a potent 3′-exonuclease activity that is optimal under nonpolymerizing conditions, such as in the absence of deoxyribonucleotides. The T4 exonuclease activity has been used to map the location of various stable lesions on DNA, including ultraviolet (UV) lesions[63,64] and BPDE-induced lesions.[48] In these studies, linear, 5′-end-labeled, adducted DNA is treated with T4 DNA polymerase in an appropriate buffer at 37 °C.[48] The reaction is terminated by heating to 65 °C for 10 min, and the resulting DNA is desalted by a spin column and resolved in a denaturing polyacrylamide gel.[48] In this procedure, however, it is difficult to decide on the exact position of the termination of T4 exonuclease, because the templates still contain the adducted base, which influences band migration in the gel. These studies indicate that T4 exonuclease can digest up to 2 or 3 nucleotides prior to the BPDE-adducted base. Unlike DNA polymerases, which progress in the 5′–3′ direction, T4 exonuclease progresses in the 3′–5′ direction. Therefore, the study of PAC reaction patterns by DNA polymerase and T4 exonuclease can provide important information about the spatial characteristics of adducts in various sequence contexts. Stable adducts are formed either in exocyclic

Figure 4 Linear amplification mapping of *anti*-BPDE-, *syn*- and *anti*-DB[*a*,*l*]PDE-reactive sites in mouse H-*ras* gene exon 2 codon 61 region. (a) A 2 µg sample of a plasmid-cloned H-*ras* gene (*p*WT) was reacted with 1 µg of the indicated PAC diol epoxides in the presence of 25% acetonitrile for 15 min at room temperature in the dark. The damaged DNA was extracted by phenol/chloroform and precipitated with ethanol. A 1 µg portion of the template was used in linear amplification reactions and a single 5′-^{32}P end-labeled primer C61F or C61R was used with a 8 : 1 combination of *Tth* and *Vent* DNA polymerase. In this technique, both stable adducts and abasic sites induced by depurinating adducts were mapped as DNA polymerase extension block sites, identified from the termination of extension (one nucleotide 3′ to the damaged base) of the complementary strand. The termination events were resolved in a 12% sequencing gel by comparison with the migration patterns of bands generated by enzymatic dideoxy sequencing (G, A, T and C). The gel was read in a PhosphorImager® (Molecular Dynamics). Linear amplification was conducted for both strands in this region. The arrow at T in the sequencing gel indicates DNA damage at the central A of codon 61 (CAA). (b) Map of PAC-reactive sites in H-*ras* exon 2. (c) Mutations identified in H-*ras* exon 2 (codons 45–66) region induced by *anti*-DB[*a*,*l*]PDE treatment of *p*WT DNA followed by PCR amplification with either *Tth* DNA polymerase or an 8 : 1 combination of *Tth* and *Vent* DNA polymerase, as described by Chakravarti et al.[13] *Anti*-DB[*a*,*l*]PDE-reactive bases are indicated by arrows. (Reproduced from Chakravarti et al. by permission of Mary Ann Liebert, Inc.)

or intercalated conformations,[20] which show differential repair activity.[21] Thrall et al. compared maps of BPDE-induced stable adducts by T7 DNA polymerase and T4 exonuclease and concluded that both procedures provide maps of comparable resolution.[48]

2.3.1.4 Exonuclease III Exonuclease III digests DNA processively from the 3′ end. It also contains AP endonuclease activity.[65] This enzyme stalls when it encounters adducted bases and is inhibited from further procession along the DNA strand. When modified DNA thus treated is separated in a sequencing gel, bands are observed corresponding to adduct-bonding sites. In these experiments, 5′-end-radiolabeled, adducted DNA is incubated with exonuclease III at 37 °C.[66] There are no reports of the successful use of this enzyme for mapping PAC/DNA reaction sites.

2.3.1.5 λ-Exonuclease λ-Exonuclease is a highly processive 5′–3′ exonuclease. It is double-strand specific and requires the presence of a 5′-phosphate, and the degradation product is a single-stranded DNA.[67] λ-Exonuclease is blocked by various forms of DNA damage, especially those which significantly alter the double helical structure of DNA. Using this enzyme, the sequence preference of BPDE/DNA,[68] *N*-acetoxy-*N*-acetyl-2-aminofluorene (AAAF)/DNA[69] adduct formation has been analyzed. These results indicate that λ-exonuclease is only transiently inhibited by adducts that make small structural perturbation, but is completely inhibited by lesions that induce large changes in duplex DNA, such as BPDE-induced stable adducts.[36,68] Since λ-exonuclease treatment generates truncated DNA that still contains the adducted base, the bands obtained from denaturing polyacrylamide gel are not sharp. The ladders produced by piperidine treatment and λ-exonuclease treatment on BPDE-adducted DNA, however, appeared to be similar, except that the λ-exonuclease ladder appeared to stop 6 nucleotides before the BPDE-induced stable adduct.[68]

Exonuclease III and λ-exonuclease maps of stable exocyclic N^2Gua adduct formation by two antitumor antibiotics, tomamycin and anthramycin, have been compared using a map constructed with an endonuclease (UvrABC exinuclease, see section 2.3.2.1).[66,70] The studies suggest that UvrABC exinuclease identifies more adducted sites than either exonuclease III or λ-exonuclease.

2.3.2 Endonucleases

PAC/DNA lesion-directed endonuclease cleavage provides another general approach to map the locations of these sites. For a recent review of the DNA structure-selective properties of nucleases, see Suck.[71]

2.3.2.1 UvrABC Exinuclease UvrABC exinuclease is an *Escherichia coli* excision repair enzyme involved in the recognition and the initial incision of a variety of bulky chemical-induced DNA damage reactions.[72–74] UvrABC exinuclease also removes O^6-methylguanine, thymine glycol and abasic sites.[75–77] UvrABC exinuclease has been commonly used for mapping experiments. This enzyme makes two incisions, one on each side of the DNA lesion, to initiate repair. For example, the exinuclease cuts seven nucleotides upstream and four nucleotides downstream to an AAF adduct.[78,79] Similar results were also obtained with BPDE-induced stable adducts (UvrABC exinuclease cuts 6–7 bases upstream and 4 bases downstream of these adducts).[80] In these experiments, radioactively end-labeled adducted DNA is incubated at 37 °C with a mixture of purified UvrA, UvrB and UvrC proteins in the presence of ATP and salts. Reactions are terminated by incubating the reaction mixture with proteinase K and DNA precipitated with ethanol (to remove salts). The resulting mixtures are resolved in denaturing polyacrylamide gels.[81] The DNA sequence context around AAF-adducted Gua residues was found to modulate the relative efficiency of UvrABC exinuclease activity. For example, of three targeted Gua residues in a *Nar*I restriction site sequence, one was excised at 77%, another at 45% and the third at 12% efficiency.[81] UvrABC exinuclease, however, was found to cut most BPDE-modified DNA sequences quantitatively, without regard for whether the adducts resided in linear or in supercoiled DNA.[80] Nevertheless, at some BPDE-modified sequences, UvrABC exinuclease could incise only at one side of the adduct.[80] Another possible limitation of the overall efficiency of the procedure is indicated by studies that suggest that UvrABC exinuclease excises only a fraction of the bulky stable adducts present in the templates.[82] Despite the demonstrated usefulness of UvrABC exinuclease in mapping the locations of bulky stable adducts in DNA, such observations undermine this approach.

2.3.2.2 S1 Nuclease The endonuclease activity of S1 nuclease has been tested on BPDE-modified DNA.[83,84] These experiments indicate that S1 cleaves at the local distortions induced by a stable adduct[83] in a non-sequence-specific manner,[85] but with a low efficiency (only 1 in 70 adduct sites are susceptible to S1 cleavage).[84] Studies with BPDE-damaged DNA indicate that S1 is not very active against single lesions but cleaves larger lesions efficiently.[86] S1 nuclease does not cleave discrete abasic sites, presumably because a single abasic site does not sufficiently denature the DNA secondary structure.[87] However, S1 can generate double-strand breaks by cutting through closely clustered abasic sites

straddling the two strands of DNA.[87] The single strand-specific endonuclease activity of S1 nuclease would be useful for mapping the locations of DNA damage, but an associated double-strand DNase activity makes the mapping experiments difficult to optimize.

2.3.2.3 Apurinic/Apyrimidinic Endonucleases AP endonucleases can be used to map the locations of PAC-induced abasic site formation (for a review, see Doetsch and Cunningham[88]). Two major classes of AP endonucleases are known. Class I AP endonucleases (AP lyase) catalyze β elimination reactions at AP sites, leaving 3′ residues. These enzymes also contain DNA glycosylase activity. Class II AP endonucleases, on the other hand, cleave 5′ to the AP site and do not contain an associated glycosylase activity. Mapping with AP endonuclease can provide a map of PAC adduct-induced base depurination sites. In addition, the comparison of maps generated by AP endonuclease and piperidine would be useful for the validation of PAC-induced alkali-labile sites. One study suggests that some alkali-labile sites are indeed AP sites.[65] Two commercially available AP endonucleases, exonuclease III and endonuclease IV (both class II enzymes), can be used for mapping PAC-induced abasic sites. In these experiments, 5′- or 3′-end-radiolabeled DNA is treated with PAC to form adduct lesions, then incubated with AP endonuclease and resolved in a denaturing polyacrylamide gel. It has been reported that the exonuclease activity of exonuclease III is inhibited in the presence of a citrate buffer,[89] but we did not obtain great success with this methodology. Treatment of exonuclease III either on circular DNA or on linear DNA with 4-bp 3′ end protrusions[90] (for exceptions, see Hoheisel[91]), appears to be a better strategy. On the other hand, endonuclease IV does not require any special DNA template preparation and can be used for cleaving the AP sites in a variety of templates.

2.4 Analysis of Mutation Spectra

A large body of evidence indicates that PAC-induced bulky stable adducts as well as abasic sites are premutagenic lesions. Studies indicate that these lesions primarily induce single point mutations. For example, in *uvr*$^-$ (excision repair deficient) bacteria, BPDE treatment (which induces bulky stable adducts almost exclusively, consisting of 98% N^2Gua and 0.7% N^6Ade adducts) has been found to induce equal proportions of frame-shift mutations and single base substitution mutations. Of the point mutations, 54% were G to T, 22% A to T and 9% each G to A and G to C changes.[92] In human cells, BPDE-induced DNA damage was found to induce 60% G to T and 15% each G to C and G to A mutations.[93] The mutational specificity is thought to be influenced at multiple levels, including the stereochemistry of the adducts, the bases flanking the lesion, and other host cell factors.[15]

AP sites are thought to be noninstructive. Studies indicate that as DNA polymerases bypass AP sites, purines are incorporated more readily than pyrimidines and dATP is more efficient than dGTP in sustaining chain elongation.[45] Some studies suggest that the affinity of dATP for template-growing chain-DNA polymerase complex, rather than the differences in the rate of proofreading excision, is responsible for the preferential A insertion across AP sites (A-rule).[94,95] The A-rule has been verified for both spontaneous and induced depurination. For example, the major form of spontaneous base loss in vivo involves Gua depurination.[96] Correspondingly, the most common mutation was G to T changes.[97] In addition, aflatoxin B1, which induces a major N7Gua depurinating adduct, also induces a high proportion of G to T mutations.[98] In *E. coli*, >50% of abasic site-induced mutations are A to T transversions.[43,97,99] In human cells, abasic sites were found to induce a majority (40%) of frame-shift deletions along with 30% G to C and approximately 15% each A to G, A to C and A to T mutations.[100]

The preponderance of single point mutations over multiple mutations induced by these types of PAC-induced DNA damage makes the analysis of mutational spectra a possible way of identifying PAC/DNA reaction sites. However, this approach is inefficient, and for reasons discussed previously would provide a low-resolution analysis of the PAC/DNA reaction. Nevertheless, mutational analysis can be used as complementary evidence for mapping experiments by more direct methods (Figure 4c).[51]

2.5 Mapping DNA Damage Induced In Vivo

One of the chief reasons for designing PAC/DNA lesion mapping experiments in vivo, is to understand whether the sequence context of a particular DNA damage contributes to the proficiency of its repair. This goal is conveniently accomplished by mapping DNA damage sites in target genes at different times. Three PCR-based methods, namely LMPCR (for a review, see Pfeifer et al.[101]), SSLPCR[102] and TTDPCR[103] have been developed for these purposes. Figure 5 shows flow diagrams of these methods.

2.5.1 Ligation-mediated Polymerase Chain Reaction

In this method, chromosomal DNA is extracted at various times after treating cells with DNA damaging agent. It is then digested with a restriction enzyme, followed by a mapping treatment to generate strand breaks at or near the damage site. The strand breaks create a ligatable 5′

Figure 5 PCR methods for mapping PAC/DNA reactions in vivo. The PCR products are resolved in sequencing gels. When PCR is carried out with one of the primer's 5′ ends radiolabeled, the bands are detected by autoradiography. Alternatively, the electrophoresced DNA is blotted onto nylon membrane and bands visualized by hybridization with gene-specific probes. ■, DNA damage; P, phosphate, A, amine; B, biotin.

end. For example, to map UV (6–4) photoproduct lesions, which are alkali-labile, DNA is treated with piperidine[104] and, to map BPDE-induced stable adduct lesions, DNA is treated with UvrABC exinuclease.[105–107] Although the site of UvrABC exinuclease excision at the 5′ side of a BPDE adduct is variable (6–7 bases), this enzyme always cuts after 4 bases on the 3′ side.[80] The 3′ incision is relevant to LMPCR. Recently, a LMPCR method to map aflatoxin B1-induced DNA depurination has been reported, in which the strand breaks are induced by treating damaged DNA with piperidine.[108] Alternatively, abasic site-specific DNA strand breaks can be induced by treating DNA with an AP endonuclease. Next, a gene-specific primer is annealed and extended with T7 DNA polymerase (Sequenase). This creates a pool of variously sized, double-stranded products that are blunt-ended at the 3′ end.

An unphosphorylated, asymmetric double-stranded linker is then ligated to the blunt end of the extended products and a PCR amplification reaction is conducted with a linker-specific primer and a nested gene-specific primer. The PCR products are resolved in a denaturing polyacrylamide gel. The LMPCR amplified break positions are detected either by radio-densitometry in a PhosphorImager® (Molecular Dynamics, CA, USA)[105] or by electroblotting the gel onto nylon membranes and hybridizing with a gene-specific probe.[104] Comparison of BPDE/DNA reactive sites in vitro with corresponding LMPCR maps suggests that, in general, BPDE reacts with DNA with similar sequence specificity both in vivo and in vitro.[105]

LMPCRs can detect a relatively small population of damaged DNA. Studies suggest that a population of 100 molecules of template DNA[109] and a lesion population more than 1 in 10 000 nucleotides, is adequate for such analysis.[110] It has been reported that the LMPCR technique could be made more sensitive by electrophoretically enriching restriction enzyme-digested chromosomal DNA to the size of the target gene.[111] In a variation of the basic LMPCR protocol, biotinylated primers have been used for the initial gene-specific extension, and subsequently biotinylated, linker-ligated molecules have been purified with streptavidin.[105] However, it is not known whether such changes help the LMPCR protocol. Nevertheless, several steps of LMPCRs could contribute to inefficient band detection.

For example, the 5′ end generated by the strand scission reaction must be phosphorylated and also the primer extension reactions must be full-length in order for blunt-end linker ligation reaction to occur. In addition, the efficiency of blunt-end ligation may determine the effectiveness of the protocol. Although the ligation kinetics of the variously-sized double-strand fragments could possibly vary, it is unlikely that individual templates will be selectively lost in order to become under-represented in steps up to linker ligation. The final PCR amplification can only compensate for the loss of uniform signal strength.

2.5.2 Single-strand Ligation Polymerase Chain Reaction

SSLPCR[102] differs from LMPCR by not requiring DNA damage-specific strand cleavage. Instead, the method depends on the DNA polymerase-blocking properties of various DNA lesions. A second difference in this protocol is the use of single-strand ligation reaction with T4 RNA ligase. In this method, chromosomal DNA is isolated from damaged cells and subjected to linear amplification with a biotinylated primer specific for a target gene. Gene-specific linear amplification enhances the overall resolution of the procedure. This results in the formation of a population of single-stranded DNA molecules that are truncated by damage-induced termination of DNA synthesis. The biotinylated single-strand DNA is captured with streptavidin and separated from free genomic DNA by washing. Using T4 RNA ligase, these molecules are ligated to a single-strand linker DNA (containing a 5′ phosphate for ligation and a 3′ amine to prevent self-ligation). Using a two-step PCR with an oligonucleotide complementary to the linker sequence (to act as the forward primer) and a 5′-end-radiolabeled second primer (nested to the linear amplification primer), one-strand radiolabeled PCR products are generated. These products are denatured by heating to 95 °C in a formamide-containing sequencing gel loading buffer and resolved in a denaturing polyacrylamide gel. Although SSLPCRs are likely to be very useful, this method has yet to be used for mapping PAC-reactive sites in DNA.

The use of T4 RNA ligase may limit the sensitivity of SSLPCRs. DNA is not a preferred substrate for T4 RNA ligase and ligation proceeds in a slow and inefficient manner, using low amounts of single-stranded DNA.[112] It has been reported that SSLPCRs gave weaker intensity bands than LMPCRs.[103]

2.5.3 Terminal Transferase-dependent Polymerase Chain Reaction

TTDPCRs were designed to overcome the perceived deficiencies of LMPCRs.[103] Like SSLPCRs, TTDPCRs also use linear amplification with a gene-specific primer, relying on the polymerase-blocking property of the DNA lesion for synthesizing truncated single-strand molecules. Next the single-stranded DNA molecules are ribo-tailed with terminal deoxynucleotidyl transferase (TDT) using rGTP.[113] The use of ribonucleotide in this reaction limits the tailing to a few residues (an average of three nucleotides).[103] Next, a double-stranded linker containing a 3′ overhang of three complementary cytosines is ligated with T4 DNA ligase. The complementary oligonucleotide of the linker contains a 5′ phosphoryl and 3′ (aminopentyl) blocking group. This ligates the recessed 5′ end of the linker with the 3′ rG tail of the linear amplified molecules. The cohesive-end ligation in TTDPCRs may be more efficient than the blunt-end ligation of LMPCRs. Next, the linker-ligated templates are PCR amplified with a nested gene-specific primer and the top oligonucleotide of the linker. The products are resolved in a denaturing polyacrylamide gel, electroblotted and hybridized with an internal gene-specific probe as in LMPCRs. UV-induced DNA damage has been mapped by TTDPCRs and LMPCRs in parallel.[103] TTDPCRs were reported to yield approximately 4–7 times stronger bands than LMPCRs.[103]

LMPCRs are the older method and have found wide acceptance. In comparison, SSLPCRs or TTDPCRs are recently described methods. Both SSLPCRs and TTDPCRs are likely to be useful procedures for mapping the sequence preferences of various types of carcinogen-induced DNA damage.

The discovery of restriction endonucleases is perhaps the most significant technical milestone in the development of recombinant DNA technology. For, together with ligation and transformation procedures, they enabled the insertion of genes of any organism in suitable vectors (e.g. plasmids), introduction of the vector in bacteria and subsequent replication of the DNA of interest during cell division (cloning). Other important technical milestones include the development of methods for DNA sequencing and the chemical synthesis of oligodeoxynucleotides.

The polymerase chain reaction (PCR) is another technique which had a major impact in every area of research that involves nucleic acid analysis. PCR is a method of exponentially increasing the concentration of a specific nucleic acid sequence in a reaction mixture. A great advantage of PCR is that the target nucleic acid does not need to be particularly pure. It can be a minute part of an extremely complex mixture of biological material. Crude cell lysates provide a very good starting material. The ability to propagate, in a few hours, minute amounts of DNA that are too small for standard amplification (i.e. cloning) techniques gives PCR an extraordinary power and sensitivity.

The advent of PCR stimulated the research activity in the development of alternative exponential amplification systems such as the ligase chain reaction (LCR), the self-sustained sequence replication (3SR), the nucleic acid sequence-based amplification (NASBA) and the strand displacement amplification system (SDA). An essential feature of target amplification techniques is that the amplification is an iterative process consisting of successive cycles. The products synthesized in one cycle act as templates for the next cycle.

Amplification techniques can be used to amplify trace amounts of nucleic acid sequences in blood, cells, water, food and other clinical and environmental samples. Fixed tissue specimens, buccal cells from mouth washes, human hair, dried blood at the scene of a crime, single lymphoid or sperm cells are examples of starting material that may be used for nucleic acid analysis.

1 INTRODUCTION

The PCR entails the in vitro enzymic exponential amplification of a specific DNA sequence from a complex mixture. Increasing the copy number of a target nucleic acid sequence greatly facilitates its detection. The method involves repetitive bidirectional synthesis of a segment of double-stranded DNA occurring in successive rounds (thermocycling) in such a way that the product of one round serves as a template for the next round. Exponential amplification of specific RNA sequences is achieved by the reverse transcription polymerase chain reaction (RTPCR). PCR can be adapted to allow quantification of a target DNA or RNA sequence originally present in the sample prior to amplification. PCR provides sensitivities which are order of magnitudes greater than Southern and Northern analysis and nuclease protection assays. Due to its extraordinary sensitivity, the PCR is the method of choice for detection of nucleic acids at very low levels. PCR has greatly facilitated the detection of inherited mutations associated with genetic disease. It has also found widespread application in the detection of infectious agents in a variety of clinical and environmental samples. Conventional means for identification

of pathogens include immunoassays for viral antigens or antiviral antibodies in the serum of patients and, in many cases, tedious and time-consuming culturing techniques that often lack the sensitivity and specificity required for routine diagnosis. PCR-based detection assays are simpler and offer much higher sensitivity and specificity. LCR, 3SR, NASBA and SDA are alternative exponential amplification systems. LCR is especially useful in mutation detection. Contrary to PCR and LCR, in 3SR, NASBA and SDA the exponential amplification is achieved in an isothermal manner. The high sensitivity of the exponential amplification techniques calls for extreme caution to avoid contamination of the samples from amplified sequences.

2 POLYMERASE CHAIN REACTION

2.1 Simple Polymerase Chain Reaction

The PCR, one of the most powerful techniques used in nucleic acid analysis and molecular biology today, was invented by Kary Mullis[1,2] who won the 1993 Nobel Prize in Chemistry for this contribution.

The principle of PCR is illustrated in Figure 1. In PCR, successive rounds (cycles) of heat denaturation, primer annealing and primer extension by a DNA polymerase result in a repetitive bidirectional synthesis of a segment of double-stranded DNA, the end result being an exponential increase in the number of target DNA copies. The sequence amplified by PCR is determined by the position of the primers. In the first heating step (~95 °C), the double-stranded DNA is denatured to form two single strands (disruption of hydrogen bonds). The temperature is then reduced to between 40 and 72 °C, thereby allowing the binding of two oligodeoxynucleotide primers (upstream and downstream) to complementary sequences on opposite strands of the target DNA fragment. The primers are oriented so that their 3′ ends point toward one another along the intervening sequence. The final temperature change of the cycle (to 72 °C) allows the 5′ → 3′ extension of each primer catalyzed by DNA polymerase. Following one complete cycle, two copies containing the sequence of interest are generated. As the cycling continues, the primers bind to the original target as well as to the newly synthesized strands and the number of target DNA copies approximately doubles at every cycle. The short products, which accumulate exponentially during PCR, are of uniform size corresponding to the distance between the 5′ ends of the two primers. The theoretical abundance of the short products is 2^n where n is the number of cycles performed. This translates to approximately one million times amplification in 20 cycles of PCR. The strands that are synthesized as copies of the original template (long products) are bounded at their 5′ end by a primer while their 3′ end is determined by the position at which the DNA polymerase stops. Strands containing undetermined 3′ termini can be generated only by copying the original template and therefore their accumulation is linear ($2n$). As a consequence, the long products are rare compared to the short product. The size and homogeneity of the PCR product can be assessed by agarose gel electrophoresis and ethidium bromide staining or by Southern blot and hybridization to labeled probes.

Figure 1 The principle of PCR. The denaturation, annealing and extension steps for the first three cycles are illustrated. The process results in exponential accumulation of the target sequence defined by the 5′ ends of the primers. At the end of the first cycle, the products are defined at their 5′ terminus (depicted as closed circles) by the primer but are not defined at the 3′ terminus. These products are termed long products. After the third cycle, the majority of the products will be defined at both termini (short products). The **x** represents a 3′ end that is defined by the primer. The arrows show the direction (5′ → 3′) of primer extension by the DNA polymerase.

The earliest PCR experiments used the Klenow fragment of *E. coli* DNA polymerase I at a temperature optimum of 37 °C, but this enzyme was easily inactivated at the high temperatures required for DNA denaturation and therefore fresh aliquots had to be added in each cycle. One of the most important developments in PCR was the introduction of Taq DNA polymerase, a thermostable DNA polymerase (temperature optimum at 72 °C) originally isolated from the thermophilic bacterium *Thermus aquaticus* (Taq) which lives in hot springs.[3] The

availability of Taq DNA polymerase has greatly simplified the automation of PCR since the enzyme is added only once, at the beginning of the reaction.[4] Furthermore, the use of Taq DNA polymerase has enhanced considerably the specificity and yield of the amplification process because it allowed the primer annealing and extension to occur at higher temperatures, thus minimizing competing mispriming events (annealing to nontarget sequences). The Taq DNA polymerase has no $3' \rightarrow 5'$ exonuclease activity (proofreading activity) but it possesses $5' \rightarrow 3'$ exonuclease activity during polymerization.[5] In situations where the PCR product is to be sequenced or sub-cloned for expression studies, the fidelity of the amplification is also crucial. Thermostable proofreading DNA polymerases (e.g. Pfu DNA polymerase) have become commercially available for these purposes.

The selection of primers is a key factor in determining the success of specific amplification. Primers are usually 20–28 bases long to permit high-stringency annealing, thus providing greater specificity. Shorter primers will yield nonspecific products and much longer sequences will result in low yield. Whenever possible, the two primers should have very similar melting temperatures to ensure that a given thermal profile is optimally efficient and specific for both primers. The G + C base composition should be about 40–60%. Intrastrand complementary regions resulting from runs of three or more G and C are inclined to form secondary structures (e.g. hairpin loops) and thus should be avoided especially at the 3′ end of the primer. Interstrand complementary regions at the 3′ ends of the primers should also be avoided in order to prevent the formation of primer dimers. This amplification artifact is a double-stranded DNA fragment whose length is equal to the sum of the two primers and appears to occur when one primer is extended by the polymerase over the other primer. Computer programs are available to aid in the process of primer selection. Primers are added in excess so that they do not become the rate-limiting factor in the reaction. The primer concentrations used range from 0.05 to 0.5 $\mu mol\,L^{-1}$. High concentrations may promote mispriming and the formation of primer dimers.

Since DNA polymerase extends the 3′ end of the primer, the 5′ end can be altered to create modified PCR products differing from the starting template. This provides a means of introducing restriction sites, specific mutations, promoters and regulatory elements (for subsequent expression). These sequences, although not complementary to the target DNA, become effectively incorporated into the final product. In a similar manner, various affinity tags or labels can be attached to the 5′ end of the primers and get incorporated into the newly synthesized strands to allow the capture and detection of the amplification products.[6]

Each of the deoxyribonucleoside triphosphates (dATP, dTTP, dCTP, dGTP) are usually present in the PCR mixtures at a concentration of 20–200 $\mu mol\,L^{-1}$. Higher concentrations are avoided because they promote mispriming at nontarget sequences (decreased PCR specificity) and misincorporation of nucleotides (decreased fidelity of DNA synthesis). The four dNTPs should be used at equal concentrations to avoid misincorporation. Like the primers, affinity tags or labels may be attached to the dNTPs and become incorporated into the amplification products for subsequent capture and detection. Mg^{2+} is bound to the dNTPs and is required for optimal activity of the polymerase. The Mg^{2+} concentration may affect the primer annealing, the denaturation temperature, PCR specificity and yield and therefore it should be optimized for each target DNA.

The inherent specificity of PCR lies in the fact that in order for exponential amplification to occur both primers must anneal, in the correct orientation, to a relatively short target DNA sequence. Moreover, after a few cycles of amplification the amount of target DNA has increased so much that less favourable competing events progressively become less frequent. The specificity of PCR may be improved further by increasing the annealing temperature and optimizing the incubation times for annealing and extension, to reduce the chances for mispriming and extension of nontarget sequences. The denaturation time and temperature should be long enough to allow complete separation of the DNA strands in each cycle, thus ensuring high yield.

A practical approach used widely to minimize the nonspecific amplification and the formation of primer dimers involves the addition of an essential reagent (e.g. DNA polymerase, primers, dNTPs or template) to the reaction mixture after it has reached high temperature, i.e. $>80\,^{\circ}C$ (''hot-start'' protocol).[7] Alternatively, the ''hot-start'' protocol may be performed by using a wax or jelly barrier that melts and permits mixing of aqueous components at a high temperature.[8] Another approach to ''hot-start'' PCR uses a monoclonal antibody that binds to and inactivates the Taq DNA polymerase at ambient temperature. This inhibition is reversed when the temperature is raised in the denaturation step of the first cycle and the enzyme functions normally during the course of PCR.[9]

The theoretical amplification of PCR (2^n) would be achieved only if the reaction could be performed with 100% efficiency (i.e. doubling of the DNA in each cycle). In practice, however, the system operates at a lower efficiency mainly as a result of an initial (lag) phase. This is attributed to a number of factors including the unavailability of the DNA target due to strand breaks, lack of its dissociation from other macromolecules, structural constraints, or a tendency of

the long parental strands to reanneal. A low efficiency during the first few cycles of PCR greatly compromises the overall yield of the reaction. Once the lag phase is overcome, the reaction enters the exponential phase. During late PCR cycles, however, the exponential rate of product accumulation decreases, a phenomenon commonly referred to as the ''plateau phase'' of PCR. The point at which the amplification reaches a plateau depends primarily on the amount of input target DNA and the number of cycles. The factors contributing to the plateau effect include competition between primer/template and template/template annealing, incomplete denaturation of the target strands and competition for reactants by any accumulated nonspecific products. Depletion and/or destruction at high temperatures of PCR reactants, such as primers, dNTPs and polymerase, as well as inhibition of PCR by end-products of the reaction, such as pyrophosphate, may also contribute to the plateau effect. The plateau phase is an unavoidable occurrence inherent to the technique.

The exquisite sensitivity resulting from the exponential amplification in PCR renders it highly vulnerable to the potential contamination of a sample by-product carried over from previous amplifications. Vigorous precautions must therefore be taken to avoid the setbacks associated with spurious amplifications.[10] Some of the common practices exercised in most PCR-performing laboratories include pre-aliquoting of reagents, use of dedicated pipettes and physical separation of the areas in which PCR samples are prepared, amplified and detected. Ultraviolet irradiation of reagent, buffers, pipettes, pipette tips and glassware is also common. Finally, the inclusion of negative (no target DNA) and positive controls in all experiments is essential for the accurate interpretation of results. The generation of false positives is a serious concern when PCR is used for diagnostic purposes.

An elegant approach used to minimize contamination involves the selective degradation of PCR product carryover.[11] Deoxyuridine triphosphate (dUTP) is added instead of dTTP in the PCR mixture and it is thus incorporated into the amplification products. If contamination is suspected, the enzyme uracil *N*-glycosylase (UNG) is added to the reaction mixture prior to thermal cycling. UNG catalyzes the excision of uracil from any potential single- or double-stranded carryover DNA (but not RNA) present in the reaction mixture prior to the first PCR cycle. The resulting abasic polynucleotides are susceptible to hydrolysis in slightly alkaline solutions (such as the PCR buffer) and elevated temperature and therefore cannot function as templates. Since UNG itself is inactivated at the high temperatures used in PCR, the amplification products generated during thermal cycling are not destroyed and can accumulate as usual. The amplified DNA can still be assayed by hybridization with complementary probes.

2.2 Nested Polymerase Chain Reaction

Nested primer PCR is a variation of PCR used to increase the specificity and sensitivity of amplification. This protocol uses two sets of primers, one set internal to the other, and amplification takes place in two PCR steps. The first PCR uses the outer set of primers to enrich the sample with the sequence of interest. The product serves as a template for a second PCR using the inner set of primers to generate a more homogeneous final product.[1] The disadvantage of this approach lies in the potential of contamination associated with opening the reaction tube, dilution (to decrease the concentration of the outer primers) and addition of the inner primer set. It is possible to perform nested PCR in a single reaction tube without dilution, in the presence of both primer pairs. This is achieved by designing the outer and inner primers to have different melting temperatures. During the first cycles only the outer primers are used and subsequently the denaturation and annealing temperatures are adjusted to allow only the inner primers to anneal.[12]

2.3 Long Template Polymerase Chain Reaction

The amplification of long fragments from genomic DNA has been a problem when using standard PCR conditions and Taq DNA polymerase. The size of PCR products generated with Taq DNA polymerase is limited to about 2 kbp. It was found[13,14] that combining the high processivity of Taq DNA polymerase with the proofreading accuracy of another thermostable DNA polymerase in a PCR allows amplification of much larger DNA templates (up to 50 kbp).

2.4 Multiplex Polymerase Chain Reaction

Multiplex PCR[15] entails the simultaneous amplification of several target DNA sequences (e.g. several regions of a large gene) in a single PCR. A unique pair of primers is designed for each target sequence. It is necessary that the primer pairs have close melting temperatures in order to avoid large variation in the amounts of amplified products. Multiplex PCR is more useful when the various target sequences exist in similar numbers in the sample. It has been applied to the diagnosis of genetic disease (e.g. muscular dystrophy), pathogen identification and forensic assays.

3 REVERSE TRANSCRIPTION POLYMERASE CHAIN REACTION

Amplification of specific RNA sequences can be accomplished by first generating a complementary copy of DNA

(cDNA) with reverse transcriptase. RTPCR has been an invaluable analytical tool for studying gene expression, monitoring various infectious agents and diagnosis and monitoring of disease.[16] Random hexamers, oligo-(dT) or the downstream PCR primer may be used as primers for the reverse transcription. The other PCR primer anneals to the generated complementary DNA strand and Taq polymerase synthesizes double-stranded cDNA which is further amplified in the usual way. The Moloney murine leukemia virus (MMLV) and the Amian myeloblastosis virus (AMV) reverse transcriptases are widely used in RTPCR. When amplifying RNA it is essential to remove the DNA present because it may serve as a template in PCR using the same primers. Undesirable target DNA should be degraded enzymically using deoxyribonuclease I. In the case of amplification of eukaryotic mRNA, the primers should be derived from separate exons so that PCR products arising from DNA are much longer, and in lower yield, because they contain intron sequences.

3.1 One-step Reverse Transcription Polymerase Chain Reaction

In this method both the reverse transcription and PCR are performed in one step (coupled) by using optimized buffer and one (or combination of) thermostable reverse transcriptase/DNA polymerase. RNA templates containing secondary structures are often difficult for viral reverse transcriptases to reverse-transcribe. The thermostable reverse transcriptases (e.g. Tth DNA polymerase) are able to synthesize cDNA at high temperatures that destabilize the secondary structures, thus providing increased sensitivity and specificity.[17]

4 METHODS FOR ANALYSIS OF POLYMERASE CHAIN REACTION PRODUCTS

The most commonly used method for analysis of PCR products is based on the electrophoretic separation of the DNA followed by staining with the intercalating fluorescent dye ethidium bromide. Quantification of the amplified DNA may then be carried out by taking the negative of a picture of the stained gel followed by scanning densitometry. Appropriate DNA markers are required in order to construct the calibration curve. The dependence of the amount of bound ethidium on the length of the DNA fragment should be taken into account when constructing a calibration curve. A major disadvantage of this method is its limited sensitivity (10 ng). Silver staining in conjunction with polyacrylamide gel electrophoresis provides higher sensitivity.

A more sensitive approach is based on the incorporation of radioactive dNTPs (labeled with ^{32}P) directly into the amplification products and detection by autoradiography of dried gels or membranes to which the products have been transferred (Southern blot). Alternatively, dNTP modified with nonradioactive labels (e.g. biotin or hapten) can be incorporated in the amplified DNA through PCR. The modified dNTP should be stable during thermal cycling. Following PCR, the mixture is electrophoresed and the fragments are transferred to a nylon membrane. The DNA is then detected by reacting with alkaline phosphatase or horseradish peroxidase conjugated to (strept)avidin. The substrates used give a color or fluorescent precipitate at the position at which the DNA is immobilized. The concentration of a modified (nonradioactively labeled) dNTP in the PCR mixture may have a significant influence on the activity of DNA polymerase. Thus, both the modified and unmodified dNTP (at an optimal ratio) should be included in the PCR mixture to ensure efficient incorporation and high yield.[18]

High-performance liquid chromatography (HPLC) with anion-exchange columns and absorbance monitoring at 260 nm has been used successfully for separation and determination of PCR products.[19] The reaction mixture can be injected onto the column directly without prior purification.

Capillary electrophoresis has been established rapidly as an efficient method for quantitative analysis of PCR products. The system consists of two electrolyte chambers connected with a separation capillary. Capillary electrophoresis is an easily automatable and rapid technique that provides qualitative and quantitative results with high resolution and low sample/reagent consumption.[20,21]

A fully automated instrument for PCR amplification and analysis of the products was developed.[39] The sample was automatically loaded, sealed, cycled in a rapid air thermal cycler and injected onto a gel filtration column for removal of salt and dNTPs followed by analysis of amplified DNA by capillary electrophoresis. A noncross-linked polymer-filled capillary was employed with automatic refilling. Detection was accomplished by laser-induced fluorescence.

The approaches described above detect all PCR products, specific and nonspecific. PCR products from clinical samples often appear on the slab gel as a number of bands, thus making difficult the identification of the correct size. Therefore, confirmation of the sequence of the specific product is usually required. This is accomplished by hybridization of the amplified DNA with complementary probes. Unlike ethidium bromide staining or direct labeling of PCR products, hybridization demonstrates the presence of the specific DNA band only.

The classical approach to DNA hybridization involves electrophoretic separation, Southern transfer and membrane hybridization using radioactive probes. Currently, however, the hybridization methods are undergoing a transition from radioactive labels to nonradioactive alternatives, which is driven by the need to enhance the sensitivity and facilitate automation while avoiding the health hazards and inconvenience associated with the use and disposal of radioactive reagents. The labels can be incorporated into the probes either enzymically (e.g. using DNA polymerase or deoxynucleotidyl transferase and modified deoxynucleoside triphosphates) or by chemical conjugation (e.g. introduction of $-NH_2$ groups into the probe via cytidine transamination and then conjugation to the reporter molecule). Generally, there are two strategies for the analysis of the hybrids. Either the reporter molecule is directly conjugated to the probe, or a ligand is attached to the probe and the hybrids are measured in a subsequent step by adding a specific, labeled binding protein. The ligand may be biotin or a hapten (e.g. digoxigenin). Labeled (strept)avidin or antihapten antibodies may then be employed for detection. Nonradioactive hybridization assays based on fluorescent, chemiluminescent or enzyme labels have been developed. Enzymes (such as alkaline phosphatase and horseradish peroxidase) are the most widely used nonradioactive reporters because they provide amplification through the high turnover of the substrate to the detectable product. The availability of a monoclonal antibody that selectively recognizes double-stranded DNA allowed the development of enzyme immunoassays for hybrids. PCR products are denatured and hybridized to immobilized probe. After washing, the hybrids are determined with an enzyme-labeled anti-double-stranded DNA antibody.[22]

Detection is usually based on fluorescence and chemiluminescence. However, the sensitivity of conventional fluorometry is restricted by the high background due to scattering, inherent fluorescence of the sample and luminescence from the cuvettes. Time-resolved fluorometry reduces the background in fluorescence measurements, thus improving the signal-to-noise ratio. This is achieved by using labels with long fluorescence lifetimes, such as the lanthanide ions Eu^{3+}, Tb^{3+}, Sm^{3+} and Dy^{3+} (Eu^{3+} is the most frequently used label). The sample is excited with a short pulse of light, from a laser or a flash lamp, and the measurement starts only after the short-lived background fluorescence has decayed.

The most successful strategy to attach Eu^{3+} to DNA is to use the isothiocyanate derivative of a complex of Eu^{3+} with an aminopolycarboxylic acid. These compounds react easily with primary amino groups that have been introduced in oligonucleotides and deoxynucleoside triphosphates. In one assay format, the PCR products are immobilized on a solid support and detected with a probe labeled with Eu^{3+}-chelate.[23] However, the complexes of Eu^{3+} and other lanthanides with aminopolycarboxylic acids fluoresce very weakly. For this reason, after the hybridization is completed, an enhancement solution is added which has a low pH (to ensure dissociation of Eu^{3+}) and contains a β-diketone (e.g. 2-naphthoyltrifluoroacetone) which is an excellent energy donor and forms highly fluorescent complexes with Eu^{3+}. The technique allows for multi-analyte assays because the four lanthanides have characteristic narrow emission bands.

A highly fluorescent Eu^{3+} trisbipyridine cryptate inclusion complex (Eu-TBP) has also been reported as a label for time-resolved fluorometric hybridization assays. In the Eu-TBP complex the bipyridine groups absorb the excitation light and, through an intramolecular energy transfer, the energy flows to the metal ion that subsequently fluoresces. Conjugates of Eu-TBP with antidinitrophenyl antibody have been prepared and used for determination of PCR products labeled with biotin and 2,4-dinitrophenol.[24] The advantage of this technique is that it allows direct determination of hybrids immobilized on a solid support without the need to dissociate the Eu^{3+}.

Another approach combines enzymic amplification with the background rejection capabilities of time-resolved fluorometry. This is accomplished by using alkaline phosphatase as a label and the phosphate ester of 5′-fluorosalicylate as a substrate. Enzymic cleavage of the phosphate group produces fluorosalicylate, which forms a long-lived fluorescent ternary complex with Tb^{3+}-EDTA at pH 12–13. The complex absorbs at a wavelength characteristic of the chelator (337 nm) and emits fluorescence characteristic of Tb^{3+}. PCR products are captured in microtiter wells and one strand is removed followed by hybridization to a digoxigenin-labeled probe. The hybrids are determined by using an antidigoxigenin antibody conjugated to alkaline phosphatase and time-resolved fluorometry.[25]

Chemiluminescence is the light emission occurring when chemically excited intermediates or products decay to the electronic ground state. Chemiluminescence provides higher sensitivity than conventional fluorometry because there is no background from excitation light.

Acridinium esters were used as chemiluminescent labels in hybridization assays. These molecules react rapidly (1–5 s) with hydrogen peroxide under alkaline conditions to produce light (flash-type reaction). The chemiluminescent decomposition of an acridinium ester involves attack of a peroxide anion at the C-9 ester to form a hydroperoxide, followed by loss of an alcoholate leaving group to produce an unstable dioxetanone. This species decomposes to CO_2 and *N*-methyl acridone in an electronically excited state. Decay of this molecule

to the ground state is accompanied by light emission at 430 nm. The *N*-hydroxysuccinimide derivative of acridinium ester reacts with primary amino groups introduced in oligonucleotide probes. Acridinium esters may be used in the analysis of PCR products either in a heterogeneous or a homogeneous assay configuration. Heterogeneous assays involve hybridization in solution and capture of the hybrids on a solid support (e.g. magnetic beads). The homogeneous assay is based on the alkaline hydrolysis of the ester bond of the acridinium molecule, rendering it permanently nonchemiluminescent. Conditions have been developed under which the hydrolysis is slow for the hybridized probe and fast for the free probe. Following hybridization, the reaction conditions are adjusted so that the excess probe is hydrolyzed and the chemiluminescence is a direct measure of the target sequence.[26]

The photoprotein aequorin has also been used as a reporter in chemiluminescence hybridization assays of amplified sequences. Aequorin is a complex of apoaequorin (a single polypeptide chain of 189 amino acids), the cofactor coelenterazine and molecular oxygen. Upon Ca^{2+} binding to aequorin, a flash-type luminescent reaction is triggered which yields apoaequorin coelenteramide, CO_2 and light at 469 nm with a quantum yield of 15%. Microtiter well-based sandwich-type hybridization assays have been developed in which the PCR product is denatured and hybridized simultaneously with an immobilized capture probe and a biotinylated detection probe. The hybrids are measured by using streptavidin–aequorin conjugates.[27]

Enzyme labels, such as alkaline phosphatase and horseradish peroxidase, can be combined with chemiluminogenic substrates for determination of amplified DNA. The adamantyl 1,2-dioxetane aryl phosphates, such as disodium 3-(4-methoxyspiro[1,2-dioxetane-3,2′-(5′-chloro)tricyclo[3.3.1.1$^{3.7}$]-decan]-4-yl)phenylphosphate (CSPD), are the most widely used substrates. Enzymic dephosphorylation of this molecule gives a phenoxide intermediate and this decomposes to produce light emission at 470 nm (glow type reaction).[28]

Electrochemiluminescence is the chemiluminescent reaction of species that are generated electrochemically at the surface of an electrode. The complex tris(2,2′-bipyridine)ruthenium (II) chelate ($[Ru(bpy)_3]^{2+}$) has been used as an electrochemiluminescent label in the analysis of PCR products.[29,30] When the voltage in an electrochemical cell becomes greater than a threshold value, the $[Ru(bpy)_3]^{2+}$ is oxidized at the surface of the anode to give $[Ru(bpy)_3]^{3+}$. Tripropylamine (TPA), which is present in large excess in the assay buffer, is also oxidized simultaneously at the electrode to $TPA^{+\bullet}$, which after deprotonation gives the strong reductant $TPA^{\bullet}$. $[Ru(bpy)_3]^{3+}$ undergoes reduction from $TPA^{\bullet}$ with production of the excited electronic state of $[Ru(bpy)_3]^{2+}$, which upon returning to the ground state emits a photon at 620 nm. An important feature of electrochemiluminescence is that the light-emitting reaction regenerates the original $[Ru(bpy)_3]^{2+}$ species which is then available to enter another cycle of oxidation and light emission. Thus, many photons are emitted from each $[Ru(bpy)_3]^{2+}$ label.

In a typical assay protocol, one of the PCR primers is biotinylated at the 5′ end. $[Ru(bpy)_3]^{2+}$ is attached to an oligonucleotide probe complementary to the biotinylated strand. Following PCR, the products are denatured, hybridized with the probe and captured to magnetic beads coated with streptavidin. A suspension of the beads is then introduced in the flow cell of the instrument (QPCR system 5000). A magnetic arm immobilizes the beads on the surface of the working electrode and allows washing with a TPA-containing buffer. Then voltage is applied and the luminescence is measured with a photomultiplier mounted closely to the flow cell. In an alternative protocol, $[Ru(bpy)_3]^{2+}$ is attached to the primer and incorporated into the amplified sequences, thus leading to double-labeled (biotin and $[Ru(bpy)_3]^{2+}$) DNA fragments that are captured to the beads and measured directly.

In recent years methods have been developed for continuous determination of the products generated during PCR, i.e. for real-time monitoring of DNA amplification.[31–33] One such approach uses the compound SYBR Green I, whose fluorescence increases upon binding to double-stranded DNA. A limitation of this method is that nonspecific products are co-determined. An alternative strategy employs an oligonucleotide probe that is labeled with a donor fluorescent molecule (6-carboxyfluorescein) at the 5′ end and an acceptor molecule (6-carboxytetramethylrhodamine) downstream a short distance. The probe is modified at the 3′ end to block its extension by the polymerase. The close proximity between donor and acceptor allows for energy transfer to occur and, therefore, no fluorescence from the donor is observed. During annealing, the probe hybridizes to the template DNA at a position flanked by the primers. However, because of the 5′ exonuclease activity of Taq DNA polymerase,[34] the hybridized probe is hydrolyzed during the extension phase of each cycle and the fluorescence increases.

A fluorometer with microvolume multisample capabilities and temperature control for real-time monitoring of PCR has been described.[35] Complete amplification and analysis requires 10–15 min (for 30 cycles). The samples are introduced in glass capillaries that facilitate heat transfer and also serve as cuvettes. The heating is by forced air.

Molecular beacons (oligonucleotide probes that consist of a stem-and-loop structure) have been used for monitoring of PCR product formation in a homogeneous

format during or after amplification. The loop part of the beacon is a single-stranded probe complementary to the target sequence. The stem is formed by extending each side of the probe with two oligonucleotide arms that are complementary to each other but unrelated to the target (the stem is a double helix). A donor fluorescent molecule is attached to the end of one arm and an acceptor molecule is attached to the other end. The close proximity between donor and acceptor in the stem structure allows for energy transfer to occur and, therefore, no fluorescence from the donor is observed. Upon hybridization of the probe region (loop) with the target sequence the double-stranded stem structure undergoes a conformational reorganization (strand separation) that places the donor and acceptor molecules far enough apart and the molecular beacon fluoresces. The dissociation of the stem strands is due to the fact that the probe–target hybrid is longer and more stable than the stem hybrid. It has been shown that the hairpin stem structure enhances the specificity of molecular beacons, enabling them to distinguish targets differing by a single nucleotide. Furthermore, several molecular beacons attached to different fluorophores can be used to monitor the accumulation of multiple targets in the same PCR.[36,37]

Oligonucleotide probes labeled with the fluorescent phthalocyanine dye La Jolla Blue were used for a homogeneous assay of PCR products by transient-state polarized fluorescence.[38] The dye has absorbance and emission maxima at 685 nm and 705 nm, respectively. Hybridization of the La Jolla Blue–oligonucleotide conjugate with the target results in longer rotational relaxation time of the hybrid and an increase in polarized fluorescence.

5 QUANTITATIVE POLYMERASE CHAIN REACTION

Perhaps the most challenging analytical problem associated with PCR is the determination of the amount of starting material, i.e. relating the analytical signal obtained from the amplification product to the initial number of target DNA or RNA molecules present in the sample prior to amplification.

The accumulation of product during the exponential phase of PCR can be described by Equation (1):

$$P = T(1 + E)^n \quad (1)$$

where P is the amount of amplification product, T is the initial amount of target DNA, n is the number of amplification cycles and E is the average efficiency of the reaction for each cycle. The theoretical value of E is 1 but usually it has a lower value. The above equation shows that, in the exponential phase, there is a linear relationship between the amount of product and the amount of input DNA. If E was constant, then determination of T could be accomplished simply by constructing a calibration curve with known amounts of a DNA standard (under constant n). The slope of the line would be equal to $(1 + E)^n$. However, the value of E depends on the sample and the reaction conditions. Moreover, small sample-to-sample variations in E lead to dramatic changes in the amount of product and large errors in estimating the initial quantity of target (especially when the cycle number is large). For instance, a 5% decrease in E (e.g. from 1 to 0.95) leads to an almost 50% decrease in the amount of product (when $n = 25$). In situations where quantitative analysis of RNA is being performed, the variation in the efficiency of reverse transcription should be taken into account.

One approach to quantitative PCR is to use an endogenous but unrelated sequence as an internal standard.[40,41] The standard is amplified with a different pair of primers either in a separate or in the same reaction tube. Thus, the ratio of the amplification products from target and internal standard is expected to be a linear function of the ratio of target DNA/internal standard molecules prior to amplification. This approach requires that the PCR for both the target DNA and the internal standard must be restricted to the exponential phase of product accumulation. If there is a large difference in the concentrations of target and internal standard, then the plateau phase will be reached much more rapidly for the one present at higher concentration and the ratio of the products will not reflect the ratio of the initial concentrations. This problem can be resolved by an appropriate dilution before PCR.

A DNA sequence from a single copy gene can be used as an internal standard for gene dosage studies. In the case of RNA determination, a cellular RNA whose expression level is constant between samples is employed. This process also corrects for inter-sample variation in RNA isolation and for any loss of template due to ribonucleases. The most widely used endogenous standards are RNAs from housekeeping genes such as β-actin and glyceraldehyde-3-phosphate dehydrogenase. Therefore, this approach provides the relative expression of the gene of interest with respect to a housekeeping gene but it does not give the absolute number of mRNA copies. A crucial assumption is that the housekeeping gene has an even rate of transcription among different tissues of an organism, at all stages of development and in all experimental treatments. However, it has been reported that β-actin mRNA concentrations increase with the malignant transformation of cells.[42]

Another approach to compensate for the variability in the efficiency is based on the co-amplification of the target

DNA or RNA with a known amount of recombinant DNA or RNA internal standard, respectively.[43,44] The internal standard is engineered to contain the same primer binding sites and to resemble as closely as possible the target sequence. Thus, any changes in the amplification efficiency are expected to affect both amplifications equally so that the ratio of the reaction products reflects the ratio of the two nucleic acid sequences in the starting mixture. Furthermore, the PCR products of target and internal standard should be distinguishable by size, hybridization or change in a restriction site. In the case of RNA analysis, RNA internal standards are advantageous compared to DNA standards because they allow compensation for any variation in the efficiency of both the reverse transcription and subsequent amplification. In the majority of reports the internal standard is designed to contain a deletion or insertion large enough to allow electrophoretic separation of the amplification products. Each DNA fragment is then quantified by ethidium bromide staining followed by scanning densitometry. In one widely used protocol, an increasing amount of internal standard is added separately to the same amount of target sequence followed by amplification. The goal is to find the amount of standard at which target and standard give an identical signal upon staining after agarose gel electrophoresis. Equal amounts of the two PCR products imply identical quantities prior to amplification. Thus, the ratios of the amplification products for target and standard are plotted as a function of the amount of internal standard and the point at which the ratio has a value of 1 is found by interpolation. The method provides absolute quantification of the target sequence. One of the main benefits of using a recombinant internal standard with the same primer binding sites as the target sequence is that it is not necessary to restrict the data acquisition in the exponential phase of amplification because the initial target to standard ratio remains the same even if the reaction proceeds to the plateau phase.

It has been shown that the amplification efficiency is inversely related to the size of the DNA.[45] Thus, the internal standard should have a similar size to the target sequence. For this reason, internal standards that differ from the target only in a restriction site have been constructed. Following amplification, the products are digested and separated electrophoretically. It has been observed however that co-amplification of DNA fragments that share considerable sequence homology leads to the formation of heteroduplexes during PCR even if their sizes are different.[45] During the annealing phase of a PCR cycle, a fraction of the single-stranded fragments of target DNA will hybridize with the complementary strand from the internal standard and vice versa. Heteroduplex formation poses serious problems with the analysis of the products by electrophoresis and HPLC. Upon electrophoresis the heteroduplexes may migrate between the target DNA and the internal standard, causing errors in the determination of the products, especially if they cannot be resolved from the homoduplexes. In the case of an internal standard having the same size as the target but differing only in a restriction site, the heteroduplexes interfere because they are resistant to digestion.

An internal standard that is distinguishable by hybridization has identical size to the target but contains a characteristic sequence to allow hybridization with a specific probe.[46,47] Analysis of the products includes a denaturation step prior to hybridization. Consequently, heteroduplex formation is not a concern for this method. Microtiter-well-based hybridization with nonradioactive detection is preferred because it facilitates automation and high-throughput analysis. One hybridization configuration involves capture of biotinylated products on streptavidin coated wells, removal of one strand with NaOH treatment and hybridization with probes specific for the target and the internal standard. Alternatively, the PCR products are denatured and allowed to hybridize with an immobilized capture probe and a labeled detection probe. Both configurations require splitting of each sample in different reaction vessels (wells). Recently, a dual-analyte chemiluminescence hybridization assay was developed for simultaneous determination of the amplified target and internal standard in the same well. The amplified target was hybridized with a digoxigenin-labeled probe and detected by using antidigoxigenin antibody labeled with aequorin. The amplified internal standard was hybridized, in the same well, with a fluorescein-labeled probe and the hybrids were determined by using antifluorescein antibody conjugated to alkaline phosphatase. Aequorin was quantified by adding a Ca^{2+}-containing triggering solution and alkaline phosphatase was measured by using a dioxetane chemiluminogenic substrate.[48]

Fluorometric methods that allow for homogeneous real-time monitoring of PCR products (as described in section 4) are also used in quantitative PCR or RTPCR. Specific probes labeled with different donor molecules and the same acceptor molecule may be used for determination of amplified target DNA and internal standard. In this approach, quantification is accomplished by measuring the number of cycles required to reach a certain fluorescent signal that corresponds to a concentration of PCR product that is clearly within the exponential phase of amplification. Indeed, by taking the logarithm of Equation (1) and solving for n, we have Equation (2):

$$n = \frac{\text{Log } P - \text{Log } T}{\log(1 + E)} \quad (2)$$

Equation (2) shows that if PCRs (performed with various amounts of input DNA) are stopped when a predetermined level of amplification product is generated, then the cycle number is linearly related to the logarithm of target DNA molecules. For Equation (2) to be valid, the PCR must be in the exponential phase of product accumulation.

Real-time quantitative PCR methods are advantageous in that they do not require post-PCR sample processing and they are easily automatable. However, the detectability of the fluorescent label is in the nanomole per liter range and the fluorescence value provides an indirect measure of the amplification product. On the other hand, post-PCR chemiluminescence and time-resolved fluorescence hybridization assays offer 1000 times higher sensitivity since they can detect amplification products in pmoles per liter.

6 IMMUNO-POLYMERASE CHAIN REACTION

Immuno-PCR is an immunoassay in which a DNA fragment is used as a label.[49] After completion of the immunoreaction, the label is subjected to PCR amplification and the products are detected by gel electrophoresis or enzyme-linked immunosorbent assay.[50]

7 LIGASE CHAIN REACTION

LCR[51] is an exponential in vitro amplification technique that employs a thermostable ligase and allows the discrimination of DNA sequences differing in only a single base pair. The principle of LCR is as follows (Figure 2): First, the DNA target is denatured at 95 °C. Then, two allele-specific oligonucleotide probes are allowed to hybridize at adjacent positions (no gap) of the sense strand of target DNA at 60–65 °C. In a similar manner, a second pair of probes hybridizes with the antisense strand of the target sequence. The junction of the primers is positioned so that the nucleotide at the 3′ end of the upstream primer coincides with a potential base difference in the target sequence. The probes are joined by ligase and the products can serve as templates in the next reaction cycle, leading to an exponential amplification process. If there is a mismatch at the primer junction, the primers will not be ligated and amplification product will not be formed. A second set of four oligonucleotides can be used in a separate reaction to detect the mutant allele.

Figure 2 Schematic presentation of the principle of the LCR. Each cycle includes denaturation, annealing of four oligonucleotide probes (rectangular boxes) to the opposite strands and ligation of the nicks.

PLCR (a modification of LCR) is used for allele-specific DNA amplification and detection using the Stoffel fragment of Taq DNA polymerase and a thermostable ligase. After DNA denaturation, two pairs of complementary but not adjacent oligonucleotides are allowed to anneal with the sense and antisense strand of the target sequence, respectively. These primers anneal so that there is a 2–3 nucleotide gap between each other. The Stoffel fragment, lacking not only the $3' \rightarrow 5'$ proofreading exonuclease activity but also the $5' \rightarrow 3'$ exonuclease activity, can fill the gap with the appropriate dNTPs and subsequently the ligase will link the nick.

The classical approach to detection of LCR products involves labeling the upstream primer with ^{32}P at the 3′ end, separation of the LCR products by denaturing gel electrophoresis and autoradiography. Another approach employs fluorescently labeled probes that allow for analysis of LCR products by using a fluorometric DNA sequencer. Microtiter-well-based methods for determination of LCR products use one probe labeled at the 5′ end with biotin and the other probe conjugated to a nonradioactive reporter molecule (e.g. 5′-carboxyfluorescein or digoxigenin).[52,53]

LCR is often utilized in conjuction with an initial PCR amplification to achieve higher sensitivity.

8 SELF-SUSTAINED SEQUENCE REPLICATION AND NUCLEIC ACID SEQUENCE-BASED AMPLIFICATION

3SR[54] and NASBA[55] are isothermal techniques for in vitro amplification of target RNA or DNA by the simultaneous concerted action of AMV reverse transcriptase, ribonuclease H (RNase H) and T7 RNA

Figure 3 Schematic illustration of the principle of 3SR and NASBA systems. P_1, primer containing the T7 promoter sequence (T7) at the 5′ end; RT, reverse transcriptase; RNase H, ribonuclease H; P_2, second primer.

polymerase. The major amplification product is single-stranded RNA but RNA : DNA hybrids and double-stranded DNA are also synthesized, although to a minor extent. The amplification steps are shown in Figure 3. The reaction begins by annealing of the first primer on the RNA target. The primer carries a T7 promoter sequence at the 5′ end. Reverse transcriptase then synthesizes a complementary DNA strand resulting in a DNA : RNA hybrid. RNase H then hydrolyzes the RNA strand of DNA : RNA hybrids thus leaving single-stranded DNA. Subsequently a second primer anneals to the DNA strand followed by the synthesis of a complementary strand of DNA by reverse transcriptase. This double-stranded DNA carries the T7 promoter sequence and serves as a template for T7 RNA polymerase that synthesizes many copies of RNA transcripts. Each of the newly synthesized RNA molecules re-enters the cycle and serves as a template for a new round of amplification leading to an exponential accumulation of the product. An amplification of 10^9 fold is achieved in about 2 h.

It has been shown that with an initial denaturation step this system could be modified to amplify DNA but the product of the reaction is always RNA. It was found[56] that the presence of dimethylsulfoxide (DMSO) and sorbitol in the reaction mixture enhances the RNase activity of AMV reverse transcriptase sufficiently to allow the reaction to proceed without RNase H. Alternatively, human immunodeficiency virus (HIV) reverse transcriptase may be used instead of AMV reverse transcriptase to allow RNase H to be omitted.

Amplification products are determined by methods similar to those used in the analysis of PCR products.

9 STRAND DISPLACEMENT AMPLIFICATION

SDA is an isothermal in vitro method for amplifying DNA sequences.[57] The technique is based on the ability of a restriction enzyme to nick the unmodified strand of a hemimodified restriction site and the ability of a $5' \rightarrow 3'$ exonuclease-deficient DNA polymerase to extend the 3′ end at the nick and displace the downstream strand. The target DNA is heat-denatured in the presence of all reagents except the restriction enzyme and the polymerase. Two primers bind to opposite strands of the DNA. At their 5′ ends the primers contain a recognition site for a restriction endonuclease (e.g. Hinc II). DNA replication using dCTP, dGTP, dTTP and dATPαS produces a double-stranded hemiphosphorothioate recognition site. Hinc II nicks the unprotected primer strand leaving intact the modified complementary strand. DNA polymerase then extends the 3′ end at the nick and displaces the downstream fragment. The polymerization/displacement step regenerates a nickable recognition site. Target amplification by SDA is exponential because each displaced strand serves as target for the other primer (i.e. the primer that was extended for synthesis of the complementary strand).

Methods for analysis of SDA products include hybridization with ^{32}P-labeled probes or nonradioactive hybridization assay configurations. More recently, fluorescence polarization was employed for real-time monitoring of SDA products.[58]

ABBREVIATIONS AND ACRONYMS

AMV	Amian Myeloblastosis Virus
CSPD	Disodium 3-(4-methoxyspiro[1,2-dioxetane-3,2′-(5′-chloro)tricyclo[3.3.1.1$^{3.7}$]-decan]-4-yl)phenylphosphate
DMSO	Dimethylsulfoxide
HIV	Human Immunodeficiency Virus
HPLC	High-performance Liquid Chromatography
LCR	Ligase Chain Reaction
MMLV	Moloney Murine Leukemia Virus
NASBA	Nucleic Acid Sequence-based Amplification
PCR	Polymerase Chain Reaction
RTPCR	Reverse Transcription Polymerase Chain Reaction
SDA	Strand Displacement Amplification
TPA	Tripropylamine
UNG	Uracil *N*-glycosylase
3SR	Self-sustained Sequence Replication

Radiation hybrid (RH) mapping is a convenient and widely used method for rapidly locating new DNA sequences on genomes in relation to other DNA markers. The aim of the technique is to determine the correct order and relative distances between a set of markers, or to locate a new marker to its most likely location on a genome. We review the history of the technique, its current status, and the main analytical techniques used to generate maps from raw data. The physical processes and assumptions underlying the technique are examined. These processes are used to derive models from which the required information, location of markers with respect to each other on a linear map of DNA, is obtained by a variety of computational means. The RH technique has proved indispensable in mapping the human genome, since, unlike genetic mapping, the conditions under which panels are made is completely under experimental control, so mapping at any degree of resolution is possible. The other major advantage of RH mapping over genetic mapping is that markers need not be polymorphic; it is presence or absence of a marker that is detected, not type. It has therefore been used to map the large numbers of expressed sequence tags that have been generated as part of the human genome project (HGP). This has given rise to the first human gene map and subsequent updates, so that currently 40 000 genes have been assigned locations on the human genome.

1 INTRODUCTION

A genetic linkage map comprises the locations and relative distances between genes and other unique DNA sequences on linear maps corresponding to different chromosomes. Genetic linkage maps are a fundamental tool in modern biological research. They enable identification, cloning and sequencing of new genes by localizing the area of the genome in which the gene is located. They also allow identification of conserved regions between genomes of different species, which can be used to identify previously undetected genes. They have been used extensively in the study of human genetic disease and economically important agricultural species (plants and livestock). High-resolution maps of the entire human genome have been constructed and are being used as the framework on which to place the complete DNA sequence at their correct positions on the genome as part of the HGP. It is expected that 95% of the human DNA sequence will have been measured by the middle of the year 2000.

The first genetic maps were constructed in the early part of this century by observing the inheritance of different traits in successive generations of natural populations or artificial crosses. More recently, this technique of ''genetic mapping'' has been superseded by the technique of ''RH mapping'', which enables many more markers to be mapped faster and using fewer resources. Many of the assumptions on which RH mapping is based derive from conclusions from genetic mapping. The most important of these are that genes are located relative to each other on linear maps, and the distances between different pairs of genes can be determined from experimental observations. The key experiments that led to these conclusions are now reviewed.

1.1 Experimental Evidence for Linear Genetic Maps

Mendel first demonstrated that individual traits of appearance could be inherited. He treated these traits (genes) as being independent of each other, and predicted the frequencies of different combinations of traits that should be observed given their independent inheritance. It was soon discovered that, rather than being independent, the genes occurred in a relatively small number of tightly linked groups. This was deduced by Bateson and Punnett, who observed significant deviations from the distributions expected from independent inheritance. Certain pairs of genes were inherited from either one parent or the other more frequently than expected. Morgan interpreted these ''linkage groups'' as corresponding to the physical chromosomes; genes on the same chromosome would be inherited more often together than independently. Drosophila was observed to have 4 linkage groups, maize 10, yeast 17, mouse 20, and human 23.

Within each linkage group, the strength of linkage between pairs of genes was observed to vary. It was quantified by observing how frequently a pair of genes were inherited from just one parent. The phenomenon of ''crossing-over'' of genetic material had been discovered to be the mechanism for sharing genes from both parents to the offspring, and was identified with the physical structures known as chiasmata. These occur during meiosis between the paired chromosomes of the parents, and function to exchange, or ''recombine'', genetic material between homologous chromosomes from the two parents, thereby achieving some mixing of genes on the corresponding chromosome in the offspring. The further apart are two genes, the more likely it is they have been exchanged by a crossover, and the weaker the observed linkage. The degree of linkage between a pair of genes was quantified by the ''recombination frequency'', θ, the fraction of offspring that contain one gene from one of the parents, and the second gene from the other parent. A genetic map unit (m.u.) was defined as that distance between genes for which the 1 product of meiosis out of 100 is recombinant, $\theta_{AB} = 0.01$. The map unit is also called a centimorgan (cM) which corresponds to a physical molecular distance of approximately 1 Mb (megabase or 10^6 base pairs) in humans. That is, 1 crossover occurs on average every 100 Mb in the human genome (see Analytical methods). Therefore, a measure of the association between two genes could be used as a measure of the physical distance separating them on a linear chromosome. It enabled estimates of physical distances between genes from observed measures of association.

1.2 Use of the Recombination Frequency to Construct Linear Maps

Sturtevant, a student of Morgan, examined whether linear maps could be constructed using the recombination frequency directly as a measure of distance between genes on the same chromosome. He found that for small values of θ, genes could be ordered on a linear map. For example, if three genes A, B, and C had recombination frequencies $\theta_{AB} = 0.01$, $\theta_{BC} = 0.03$, and $\theta_{AC} = 0.04$, the correct order and distances between adjacent markers is A–(0.01)–B–(0.03) C. However, for larger values of θ, it was observed that it underestimated distances, and genes could no longer be arranged linearly. For example, if $\theta_{AB} = \theta_{BC} = 0.2$, then θ_{AC} would typically be $\sim$0.3, and the markers could no longer be accurately represented on a linear map. θ reaches a maximum value of 0.5 when the genes are completely unlinked on separate chromosomes.

The nonlinearity of the recombination frequency for larger values was explained by the occurrence of more than one crossover in larger intervals. A double

crossover would be counted as a nonrecombinant, and the recombination frequency would therefore underestimate true physical distance. The relationship between recombination frequency and physical distance is examined further in Analytical methods. These discoveries made in genetic mapping with respect to the relationship between the observed association and physical distance were of fundamental importance for the interpretation of results from RH mapping.

Although many genes have been mapped using classical genetic mapping, a fundamental limitation of the technique is the requirement that the gene should be polymorphic, i.e. show measurably different forms such as in eye color or flower shape. Many genes in the genome are thought not to show detectably variant forms, and therefore cannot be located on the genome using genetic mapping.

1.3 Somatic Cell (Goss–Harris) Mapping

An entirely different method for determining linkage between genes and the corresponding distances between them was demonstrated in 1975 by Goss and Harris.[1] Rather than relying on observations of naturally occurring crossovers to quantify linkage between genes, they physically disrupted human chromosomes by irradiating whole cells with X-rays. Linkage could then be detected by how much the genes were randomized in the process. The result of irradiation was a series of chromosomal fragments, whose size was dependent on the X-ray dose; larger doses caused more fragmentation and smaller fragments. These fragments were then fused with unirradiated hamster cells to form so-called ''somatic cell hybrids'', i.e. nongermline cells which contained DNA from two different species. A number of individual hybrid cells were cultivated, each hybrid containing an independent and random sample of the fragments. In the original experiment, the initial cells of each hybrid colony were selected if they retained human fragments expressing the enzyme HGRT (hypoxanthine guanine phosphoribosyl transterase), by growing on HAT (hypoxanthine, aminopterin, thymidine) medium. This complemented the lack of HGRT, which is located on the long arm of the human X chromosome. Hamster cells that did not retain chromosomal fragments containing HGRT did not survive the selective medium. The frequency with which three other human genes on the X chromosome were co-transferred with the selected marker was measured, and interpreted in terms of how strongly ''linked'' they were. The data showed that one of the genes (PGK) segregates from the selected gene (HGRT) more frequently than do the other two genes (α-gal and G6PD). This was interpreted as due to PGK being further apart from HGRT than are the other two genes, since the closer that two markers are together, the less likely it is that they will be separated by X-rays. A quantitative treatment was developed[1,2] which allowed distance, in units of the mean number of breaks that occur between pairs of markers, to be estimated directly from the observed frequency of coretention in the hybrid panel. From these observations, Goss and Harris were able to determine the order and relative distances between the four genes.

In a second experiment, Goss and Harris[3] constructed a human–mouse panel, which retained fragments even if they did not contain a selected gene such as HGRT. The analysis became more involved, since a hybrid typed positive for two genes could be due to their dependent retention on the same fragment or independent retention of both genes on different fragments. Methods were developed by which the observed distribution of the number of different hybrid types could be used to estimate distances between pairs of markers. Mapping of any region of the genome could be accomplished with this panel, since the restriction of having a selectable marker had been removed. Their quantitative treatment of the observations is described in Analytical methods.

1.4 Radiation Hybrid Mapping

The method was underused until its revival in 1989/90 by Cox et al.[4,5] This was attributed to a lack of sufficient markers to exploit the technology.[6] Cox et al.[4] constructed a human–hamster hybrid panel which also contained human fragments without the need for specific selection. Their approach differed slightly from Goss and Harris's nonselective method by using a rodent–human somatic cell hybrid that contained a single chromosome as the donor cell, rather than a diploid human cell. The advantage of this technique was that all fragments retained in the RH were known to originate from a single known human chromosome. They demonstrated the technique by localizing a 10–20 Mb region on chromosome 4 in the region of the Huntington Disease gene.[4] It was subsequently used to map 20 genes on the proximal half of chromosome 21[5] and 21 genes on the distal half.[7] The authors also generated expressions relating retention frequencies to physical distances, along similar lines to Goss and Harris.[1] These are described in Analytical methods. Some differences between genetic mapping and RH (Goss–Harris) mapping are shown in Table 1.

1.5 Whole-genome Radiation Hybrid Mapping

Walter et al.[8] returned to the original methods of Goss and Harris, by using as a donor cell a diploid human cell (fibroblast) rather than a human–rodent hybrid cell

Table 1 Differences between genetic and RH mapping

Property	Genetic	RH
Measured variable	Allele	+/−
Means of segregation	Chiasmata	X-rays
Meaning of θ	''Recombination frequency''	''Breakage frequency''
What is sampled	No. of recombinant offspring	Coretention of marker pairs
Experimental control	No	Yes

containing a single human chromosome. This enabled mapping of all regions of the human genome, not just a single chromosome, using a single RH panel.

1.6 Growth of the Field

Following the publication of the 1990 Cox paper,[6] there was enormous renewed interest in the technique, stimulating many new studies and the development of many new analytical techniques. This was partly due to the large number of novel markers that had been generated in the early 1990s for the construction of high-resolution genetic maps of the human[9] and mouse[10] genomes. These unique DNA sequences were readily available for independent mapping using the complementary technique of RH mapping. Since the underlying order and physical distances between markers on chromosomes is thought to be largely constant, comparison of the maps generated by genetic mapping and RH mapping would reveal important differences between the techniques. An example would be the identification of regions of the genome that have a higher occurrence of crossovers (recombination ''hot-spots'') which would inflate distances on the genetic map with respect to the corresponding region on the RH map. Such ''hot-spots'' have often been implicated in disease. These studies continue as data accumulates.

The considerable theoretical background developed for genetic mapping was also used with some modifications in the development of new techniques for analyzing results from RH experiments. Therefore, although the physical processes underlying RH mapping are fundamentally different from those in genetic mapping, the analytical techniques used rely heavily on previous results from genetic mapping work.

2 CONSTRUCTION OF A RADIATION HYBRID PANEL IN SILICO

The processes occurring during construction of an RH panel can be visualized using Monte Carlo simulation techniques. We follow the steps of the experiment in silico as they are thought to occur in vitro.

1. We assume a 1–1 relationship between an irradiated cell and the recipient hybrid cell that will ''retain'' the fragments of the donor chromosomes. For a panel comprising 50 hybrids, we assume that each of the 50 recipient cells ''retains'' the fragments resulting from irradiation of 1 of 50 donor cells. The 50 donor chromosomes are represented as vertical lines in Figure 1(a).
2. Each of the donor chromosomes is independently irradiated, causing the donor chromosome to break at random and independent locations. The number of breaks occurring on a chromosome is proportional to the X-ray dose and the length of the chromosome. We chose a chromosome of arbitrary length 5, meaning that on average there are five breaks per chromosome. The actual number of breaks is chosen from a Poisson distribution with mean and standard deviation equal to 5, and this number of breaks is placed uniformly randomly on the chromosome. The positions of the breaks on each chromosome are represented as small horizontal lines.
3. Each recipient cell ''retains'' a certain fraction of the fragments of its donor chromosome by randomly selecting them from the fragment pool generated by breakage. This fraction is chosen to correspond to experimentally observed marker retention frequencies. Here we choose the retention frequency to 0.5, which maximizes the information provided by each marker. Retained fragments are drawn in black in Figure 1(a); fragments not retained are drawn in gray.
4. The positions of 50 randomly placed markers are shown at the right-hand edge of Figure 1(a).
5. Each of these markers is ''typed'' on each of the recipient hybrid cells for presence or absence, and the result is shown in Figure 1(b), in which each row corresponds to one marker, and each column is one recipient hybrid cell. Black indicates presence of a marker in a hybrid cell, and white absence.
6. In general, marker order is not known, so the order of markers in Figure 1(b) is randomized in Figure 1(c) (the rows are scrambled). Figure 1(c) is a typical starting point for construction of a chromosome map using RHs, with the rows in arbitrary order, i.e. the markers are in no particular order.

The goal of an RH panel, starting from Figure 1(c), is to determine the correct order of markers (Figure 1c → Figure 1b). Then the correct distances between adjacent markers should be obtained (Figure 1b → Figure 1a).

Figure 1 Simulation of an RH experiment. (a) Individual chromosomes are fragmented with X-rays, average of five breaks per chromosome, defining its length as 5R (5 Rays where 1 Ray is the distance interval in which 1 break occurs on average; 5 Rays is the distance in which 5 breaks occur on average). Positions of breaks are indicated on each column (chromosome) by small horizontal lines. Fragments are retained (black lines) or lost to the medium (gray lines). (b) Fifty markers are placed randomly on the chromosomes (at the same positions on each chromosome). These positions are indicated by short horizontal lines at the right-hand edge of (a). The lines joining (a) to (b) remove the interlocus distance information. The actual positions of the markers are on the left, their order on the right. The histogram to the right of (b) shows the number of chromosome breaks that have occurred between adjacent loci. Large numbers of breaks are clearly reflected as horizontal discontinuities in the marker retention pattern. (c) The order of the markers is randomized, and it is usually in this form that raw data exist before any mapping. There are 89 obligate breaks in the ordered set, and 759 in the randomized set.

3 ANALYTICAL METHODS

The process of constructing a map from experimental data involves two steps: detection and quantification of linkage in terms of physical distance between pairs of markers, and subsequently placing the markers on a linear map which best explains the physical distances. Many different methods have been developed, typically first for meiotic linkage mapping, since it has been in practice for much longer than RH mapping, then subsequently applied with modifications to RH data.

The experimental data from both meiotic mapping and RH mapping is used initially to determine whether there is any association between pairs of markers. Association can be quantified in two respects: the strength of the association; and its significance. The strength of association is greater for markers closer to each other, and can therefore be used as a measure of physical distance. It is measured as θ, the recombination frequency in genetic mapping or the breakage frequency in RH mapping, between a pair of markers. The significance of the association measures how likely the observed association would be to arise by chance, and is used to attach some ''confidence'' to the associated strength, and is usually expressed as a log-of-odds (lod) score, denoted $Z(\theta)$, which is the log of the likelihood of obtaining the observed value of θ if the markers were not linked. The significance of an observation increases with the number of samples taken (e.g. number of offspring in a genetic cross or number of hybrids in a RH panel), and allows weaker associations to be measured with more confidence that they are not due only to random fluctuations.

3.1 Strength of Linkage in Meiotic Maps

Results from genetic crosses indicated that certain pairs of genes appeared to be inherited together more frequently than would be expected if their inheritance were independent. The degree of linkage (or its complement, random inheritance) was quantified by counting the number of offspring that inherited genes from different parents (recombinants). These arise from the occurrence of ''crossovers'' during meiosis, which exchange genetic material between the parental chromosomes. Analysis of the structure of crossovers, which indicated a strictly reciprocal exchange of genetic material, shows that if two markers are separated by 1 *or more* crossovers, the frequency of recombinants in the offspring will be 0.5. If two markers are not separated by a crossover, the frequency of recombinants (recombination frequency) is 0.0. Intermediate values of the recombination frequency

are then determined by the probability that 1 or more crossovers have occurred between markers. The reciprocal exchange of genetic material from the two parents at each crossover enables θ to be estimated directly from the number of recombinant offspring.

Haldane[11] assumed that crossovers occurred randomly and independently of each other. The number of crossovers in a given interval is then given by the Poisson distribution. If the rate of occurrence of crossovers in a unit interval of distance is λ, then the probability of observing n crossovers in a given interval with length D is given by Equation (1)

$$p_n = \frac{1}{n!}\lambda^n e^{-\lambda D} \tag{1}$$

In particular, the probability that no crossovers have occurred between two markers separated by a distance D is given by Equation (2)

$$p_0 = e^{-\lambda D} \tag{2}$$

and its complement, the probability that one or more crossovers have occurred in the interval D, is given by Equation (3)

$$p_{>0} = 1 - e^{-\lambda D} \tag{3}$$

Since for 1 or more crossovers, the recombination frequency θ is always 0.5, it can be expressed by Equation (4) in terms of physical distance as

$$\theta = 0.5\left(1 - e^{-\lambda D}\right) \tag{4}$$

from which distance is obtained from the observed recombination frequency as shown in Equation (5)

$$D = -\frac{\ln(1 - 2\theta)}{\lambda} \tag{5}$$

We now have expressions relating the experimental observation (θ) to the underlying physical cause (the distance between the markers), by assuming a model in which crossovers occur randomly and independently of each other. The relation above between physical distance and θ is known as the ''Haldane mapping function''. The units of distance are the mean number of crossovers which have occurred between the markers and is not bounded, whereas θ is bounded in the interval $[0, 0.5]$, and is a good measure of distance only for small values. It is now known that crossovers occur on average every 100 Mb in the human genome, and every 200 Mb in the mouse genome, giving $\lambda = 0.01\,\text{Mb}^{-1}$ in human, and $\lambda = 0.005\,\text{Mb}^{-1}$ in mouse.

The two domains of θ and D are different. θ is a frequency, is dimensionless, and lies in the range $[0, 0.5]$. D is a distance measure, has units of mean number of crossovers, and is not bounded. Thus θ is not additive, whereas D is, and in general θ should not be used as a measure of distance, but first converted to the additive distance measure using Haldane's mapping function.

The assumption that crossovers occur randomly and independently is now known not to be strictly true, since the occurrence of a crossover at one location can inhibit formation of crossovers in its vicinity, a phenomenon known as ''interference''. Therefore physical distances between close markers are underestimated. Also, some regions of the genome are known to be more susceptible to crossovers. Recombination frequencies in these ''recombination hotspots'' overestimate true physical distance. However, the basic assumption does provide a means of relating recombination frequency to physical distance which is valid over a large range of distances, and relates directly to subsequent analytical methods developed for RH mapping.

3.2 Strength of Linkage in Radiation Hybrid Experiments

The RH experiment is another means of detecting ''linkage'' between genes. Here, the strength of linkage is detected by measuring the degree of disruption between genes induced by controlled radiation-induced chromosome breaks, and counting the number of ''offspring'', in this case human–rodent hybrid cells which retain a fraction of the resulting chromosomal fragments. The principle is that the closer two markers are together on the genome, the less likely it is that they will be separated by X-rays.[1] Therefore markers close to each other show highly correlated patterns of retention across the cells of the hybrid panel. Again, breaks are assumed to occur randomly and independently. This assumption appears to be valid in the case of RH mapping, although there are some reports that certain regions of the genome are more susceptible to breakage than others. However, we will not consider this. In contrast to determining which parent the genetic material in the offspring originates from, the experiment is to determine *presence* or *absence* of pairs of markers in a number of independent clones which retain fragments. The average retention frequency of a marker across the panel is the frequency of hybrids retaining the marker, lies in the range $[0, 1]$, and differs from panel to panel. This is in contrast to genetic mapping, in which the probability of retaining a gene from one particular parent is always 0.5. This adds an additional level of complexity to the analysis of an RH experiment.

We define formally here the ''breakage frequency'' as the probability that two markers have been separated by radiation, i.e. the probability that 1 or more breaks have occurred between them. If the physical distance between them is D and breaks occur at a rate λ, the breakage

frequency θ is determined by the Poisson distribution, and is given by Equation (6)

$$\theta = 1 - e^{-\lambda D} \tag{6}$$

from which Equation (7) gives the distance obtained

$$D = -\frac{\ln(1-\theta)}{\lambda} \tag{7}$$

The normalizing rate factor λ enables conversion of distances in terms of mean number of breaks to other units, e.g. Mb. As in meiotic mapping, the two domains of θ and D are different. Here, θ is the probability, lying in the range $[0,1]$, that a pair of markers have been separated by a break, whereas D is the number of breaks that occur on average between them, and its range is not bounded.

The problem then is to estimate θ between two markers from the results of an RH experiment, which comprise the numbers of hybrids typed AB, Ab, aB, and ab for all pairs of markers A and B (Figure 2). When markers are so close that they are never broken apart, A and B are always found on the same fragment which can either be retained by a hybrid cell, which will then be typed AB, or not retained (hybrid is typed ab), that is $p_{AB} = p_A = p_B$, and only concordant classes AB and ab are observed. If the breakage frequency is 1, A and B are always on different fragments, and assuming that fragments are retained independently, the retention of markers A and B will also be independent, i.e. $p_{AB} = p_A p_B$. For intermediate values of θ, the numbers of hybrids typed AB arise from dependent retention of A and B on the same fragment and independent retention on different fragments (Figure 3). The estimate of θ is therefore not as simple as for meiotic recombination-based mapping.

Figure 2 Relative frequencies of the types AB, Ab, aB, and ab expected for different values of θ (A,a–top, bottom row; B,b–left, right column): (i) $\theta = 0$; (ii) $\theta = 0.5$; (iii) $\theta = 1.0$. The retention frequencies of A and B are both 0.5. In (i), A and B are never broken apart, and markers are either retained or not retained on the same fragment, and only the concordant classes AB and ab are seen. In (iii), markers A and B are always on different fragments, retention of A and B is independent, and the frequency of all four classes is equal. Intermediate values of θ are apparent as a surplus of concordant types over discordant types.

Figure 3 Composition of fragments in the four hybrid types AB, Ab, aB and ab. Type AB contains fragments containing A and B together, and fragments which contain either A or B. Type Ab contains fragments which contain only A, and type aB contains fragments which contain only B. The retention frequency of A is the sum of the frequencies of the classes AB and Ab. The retention frequency of B is the sum of the frequencies of the classes AB and aB.

In the following section it is useful to remember that the experimental observations, the numbers of hybrids typed AB, Ab, aB and ab for each pair of markers, are the result of two separate processes: (1) the fragmentation of chromosomes by X-rays; and (2) random retention of a subset of these fragments in a series of independent hybrid cells, which are then subsequently typed.

3.3 Estimation of θ by Goss and Harris (1975)

In the original Goss–Harris radiation-fusion experiment,[1] the co-retention of markers with one selected marker was measured by counting their co-occurrence in a series of independent samples (human–hamster hybrids). If the marker was separated from the selected marker by a "segregation event", i.e. chromosomal break, it was lost from the hybrid. Then θ is obtained directly from the frequency with which the selected marker occurred without the second marker as shown in Equation (8)

$$\theta = \frac{\mathrm{Ab}}{N} \tag{8}$$

The distances of all markers from the selected marker were measured as $D = -\ln(1-\theta)$, and the relative order of markers was inferred from these distances.

In a second a experiment,[3] the restriction that markers be linked to a selectable marker was removed, by using

human–mouse hybrids which were known to retain human chromosomal fragments in the absence of any selective pressure. This type of hybrid therefore allows mapping in any region of the human genome. The estimate of θ using this panel became more involved, since the observation of two markers in a single hybrid could be due to both dependent coretention on the same fragment and independent coretention on two different fragments. They examine the likely composition of fragments of different types (AB together, A and B on separate fragments) in a hybrid observed to contain both A and B. The frequency with which individual fragments of whichever type are retained in the hybrid was estimated from the data as Equation (9)

$$r = \frac{r_A + r_B}{2} \tag{9}$$

where r_A, r_B are the frequencies with which A and B are observed in the clones. The frequency of clones showing discordant expression of A and B (the frequency of clones expressing either A or B but not both) is then given by Equation (10)

$$r_{Ab} + r_{aB} = 2r(1-r)\theta \tag{10}$$

If A and B were originally on different chromosomes then $\theta = 1$, and Equation (11) gives

$$r_{\text{discordant}|\theta=1} = 2r(1-r) \tag{11}$$

It follows in Equation (12) that

$$\theta = \frac{r_{Ab} + r_{aB}}{r_{\text{discordant}|\theta=1}} \tag{12}$$

i.e.

$$\theta = \frac{r_{Ab} + r_{aB}}{2r(1-r)} \tag{13}$$

Equation (13) when r is expanded gives Equation (14)

$$\theta = \frac{r_{Ab} + r_{aB}}{r_A + r_B - (r_A r_B + (r_A^2 + r_B^2)/2)} \tag{14}$$

The authors express the relation between breakage frequency and distance as $D = -\ln(1-\theta)$ using the Poisson distribution, from the assumption of random and independent breaks. Central to this analysis is the estimate of frequencies of retention of different fragments, which is observed only indirectly through the retention of markers. The significance of linkage was measured from the χ^2 statistic with one degree of freedom.

3.4 Estimation of θ by Cox et al. (1990)

The Goss–Harris mapping technique was revisited and modified,[4,5] and the technique was named "RH mapping". Analytical expressions were introduced for estimating θ from the number of discordant clones, along similar lines to the formulation of Goss and Harris.[1–3] The authors also estimate the frequency of retention of different fragments. Their reasoning is as follows. The observed marker segregation could be defined in terms of four unknowns: θ, p_A, the probability of retaining a fragment containing A but not B, p_B, the probability of retaining a fragment containing B but not A, and p_{AB}, the probability of retaining a fragment that contains both A and B.

The fraction of all hybrids retaining marker A but not marker B is represented in Equation (15) in terms of these parameters as

$$\frac{A^+B^-}{N} = \theta p_A(1-p_B) \tag{15}$$

Similarly, Equations (16–18) give

$$\frac{A^-B^+}{N} = \theta(1-p_A)p_B \tag{16}$$

$$\frac{A^+B^+}{N} = (1-\theta)p_{AB} + \theta p_A p_B \tag{17}$$

$$\frac{A^-B^-}{N} = (1-\theta)(1-p_{AB}) + \theta(1-p_A)(1-p_B) \tag{18}$$

Using just the expressions for Ab and aB gives Equation (19)

$$\theta = \frac{p_{Ab} + p_{aB}}{p_A + p_B - 2p_A p_B} \tag{19}$$

But as the authors state, it is not possible to estimate p_A or p_B from the observed data, since the experiment types hybrids for presence or absence of markers, not for presence or absence of *fragments* of certain types (AB, A, or B). They suggested using the observed frequencies of markers A and B (r_A, r_B) as estimates of the unmeasurable quantities p_A and p_B. The expression for θ can then be given by Equation (20).

$$\theta = \frac{r_{Ab} + r_{aB}}{r_A + r_B - 2r_A r_B} \tag{20}$$

The use of r_A as an estimate of p_A was justified by observing that these numbers, when substituted into Equations (15) and (16), gave ratios of the discordant types Ab/aB that were not significantly different from the observed ratios. But r_A is the total retention of marker A whether or not it is on a separate fragment to B, and therefore overestimates p_A by the frequency with which A occurs together with B on the same fragment

(Figure 3). p_B is similarly overestimated. Therefore the second term of the right-hand side of Equation (15) over-contributes to the estimate of Ab, and the third term under-contributes. These effects might therefore cancel each other out, giving the observed approximate agreement with the data. However, their final expression can be derived by other means, and it can be seen that it is identical to that of Goss and Harris, if the equality $r_A r_B = (r_A^2 + r_B^2)/2$ holds. This is the case when $r_A = r_B$, since Goss and Harris estimated only one fragment retention frequency as the average of the retention frequencies of the two markers.

Cox et al. also use the assumption of random and independent occurrence of chromosome breaks to relate θ to physical distance, $D = -\ln(1-\theta)$, i.e. the mapping function derived above, but without the ''rate'' parameter λ. The units of distance are therefore ''mean number of breaks''. They define a new unit of distance, the centiray (cR) which is equivalent to $D = 0.01$, by analogy with the centimorgan in meiotic mapping. The rate parameter is introduced as a subscript corresponding to the dose; $1\,cR_{3000} = 0.01$ breaks at a dose of 3000 rad, $1\,cR_{8000} = 0.01$ breaks at a dose of 8000 rad. The use of the mapping function converts breakage frequency to number of breaks, but requires some calibration for panels constructed with different X-ray doses.

The significance of the estimated breakage frequency was expressed as the likelihood of obtaining the observed data, given the model of fragment retention:

$$L_\theta = [(1-\theta)r_{AB} + \theta r_A r_B]^{AB}[\theta r_A r_b]^{Ab} \times [\theta r_a r_B]^{aB}[(1-\theta)r_{ab} + \theta r_a r_b]^{ab}$$

where r_{AB} is an estimate of p_{AB}, the probability of retaining a fragment containing A and B together, estimated as $r_{AB} = \{[(A^+B^+)/T] - \theta r_A r_B\}/(1-\theta)$. This was compared with the likelihood expected if θ were 1 (markers completely unlinked) to give a likelihood ratio of linkage versus nonlinkage.

3.5 Estimate of θ Directly from the Observed Marker Retention

We tried a different approach, choosing not to model the unobserved probability of retaining different types of fragment, but to use only the observed data, i.e. the frequencies of retention and coretention of markers to estimate the expected frequencies of the discordant hybrid types Ab and aB.[12] We reasoned as follows, using only the two most basic assumptions of the RH experiment: random and independent occurrence of breaks, and random and independent retention of the resulting fragments.

For a hybrid typed Ab, marker A is necessarily on a different fragment to B. The probability of retaining a fragment that contains just A is the product of the probabilities of two independent events, retention of A and retention of A separate from B. The probability of retaining A is estimated from the data as r_A. The probability that the retained fragment contains A and not B is θ, since the fraction of all fragments containing A but not B is θ, by definition of θ as the frequency with which A is separated from B. The probability of retaining A on a separate fragment to B is therefore θr_A. The probability of not retaining B in any single hybrid in the panel is estimated from the observations as $1 - r_B = r_b$. Assuming independent retention of fragments, the expected frequency of the hybrids typed Ab is $p_{Ab} = \theta r_A r_b$, and similarly, $p_{aB} = \theta r_a r_B$. The total expected frequency of the discordant classes is then $\theta(r_A r_b + r_a r_B)$. Equating the expected frequencies with the observed frequencies r_{Ab} and r_{aB} gives an estimate of θ, as shown in Equation (21), which uses the frequency of the discordant types (r_{Ab}, r_{aB}), and individual marker retention frequencies (r_A, r_a, r_B, r_b),

$$\theta = \frac{r_{Ab} + r_{aB}}{r_A r_b + r_a r_B} \tag{21}$$

Here we observe that substituting $r_a = 1 - r_A$ and similarly for B in Equation (21) we obtain Cox's expression (Equation 20), but obtained using only the observed frequencies and not requiring any substitution of unobservable frequencies. It needs no model of fragment retention other than that fragments are retained randomly and independently. A more detailed formulation based on information theory, and using additionally the frequencies of the concordant types, was described,[12] and mapping tools based on these measures are available on the Web.

Distance was obtained from θ using the mapping function $D = -\ln(1-\theta)$, assuming that breaks occur randomly and independently. The variance of the distance estimate was calculated from the law of errors of functions[13] as Equation (22)

$$\sigma^2(D) = \left\{\frac{\partial}{\partial\theta}[-\ln(1-\theta)]\right\}^2 \sigma^2(\theta) \tag{22}$$

which simplifies to Equation (23)

$$\sigma^2(D) = \frac{\theta}{(1-\theta)N} \tag{23}$$

The variance is 0 when $\theta = 0$, $D = 0$, and ∞ when $\theta = 1$, $D = \infty$, as expected. This expression for the variance is useful for other analytical procedures such as weighted least squares fitting.

If the denominator of Equation (21) is replaced by the expression of Goss and Harris (Equation 11), for their estimate of the frequency of retention of *fragments*

containing A or B, we get Goss and Harris's expression for the breakage frequency. However, this requires that the retention frequencies of A and B are equal, which is not generally true.

The significance of linkage we measured as the probability of the χ^2 statistic for a 2×2 table

$$\chi^2 = \sum_{XY} \frac{(N_{xy} - n_{xy})^2}{n_{xy}}, \quad X \in \{A, a\},\ Y \in \{B, b\} \quad (24)$$

where N_{xy} are the observed numbers of the different classes, and $n_{xy} = N_x N_y / N$ are the expected numbers if the markers were retained independently. The statistic measures the probability that the observed numbers of the four hybrid types AB, Ab, aB, and ab could have been obtained if A and B were always retained independently on different fragments ($\theta = 1$). The probability of the observed χ^2 is obtained from the incomplete β function.[14] Small values for this probability indicate that it is unlikely that the observed distribution could be obtained by independent retention of A and B, and is therefore a likelihood ratio for nonlinkage versus linkage. Its negative logarithm is exactly equivalent to a lod score for linkage. We used the χ^2 statistic to obtain pairwise lod scores between markers.[12]

3.6 Estimate of θ Using Maximum Likelihood

The requirement for estimates of the frequencies of retention of different fragments containing A and B on the same fragment used by Cox et al.[5] prompted further work to estimate these frequencies by other means, since it now seemed that fragment retention had to be estimated in order to estimate θ. These other methods are now the basis for several software packages.

One means of estimating fragment retention frequencies was maximum likelihood (ML) used by Boehnke et al.[15] ML methods had previously been used in genetic mapping,[16–22] where map distances were optimized to maximize the probability of the observed data. They were again applied in the field of RH mapping.[15] Application of ML methods involves first constructing a model of the process assumed to be occurring, and estimate the values of the parameters by maximizing the likelihood of the data, given the model parameters. Parameters to ML models are breakage frequencies between all pairs of loci, and retention frequencies of different-sized fragments containing more or fewer markers on the same fragment depending on the fragment size. A breakage frequency θ_i is the probability that a break occurs between markers i and $i+1$. The retention probability p_{ij} is the probability that a fragment containing loci i, $i+1, \ldots,$ and j is retained in a RH. Trial interlocus distances are included in the calculation until a distribution of breaks across each chromosome is obtained that maximizes the likelihood of the observed distribution of markers across all hybrids in the panel. Likelihood methods therefore estimate distances between markers, and attach a likelihood to a given order of markers. ML methods require a means of scanning through the $N!/2$ possible orders to optimize the model. Boehnke et al. used Expectation maximization.[23]

The number of parameters that are adjusted is large: for N markers, there are $N(N-1)/2$ different probabilities of retaining each different pair of markers on the same fragment. This makes ML computations expensive. To reduce the computational burden, Boehnke et al.[15] restricted the ways in which fragment retention p_{ij} was parameterized in the model to a small number of classes. These were (1) the equal retention frequency model, which assumes that all fragments containing all different pairs of markers were retained with equal probability, (2) moving-average model, in which the retention probability is the average value of the retention frequencies of all markers on the fragment, (3) Markovian models, chosen for the availability of rapid computational treatments for Markov chains, (4) centromeric or telomeric model, in which a fragment containing the centromere is retained with one constant frequency which is higher than that for all other fragments that do not contain the centromere, and (5) the left-endpoint model, in which the retention frequency is chosen to be the retention frequency of the marker closest to the centromere. The last two models were introduced since it was observed that marker retention probabilities for the Cox et al.[4] 21q RH data decreased with increasing distance from the centromere.

The models therefore have the capacity for becoming extremely complex, and it is worth remembering here what is actually occurring. Retention frequencies of different fragments are chosen on the basis of their assumed location on the chromosome, and subsequently inter-marker distances are optimized to maximize the likelihood of the data. However, the normal case in mapping is that at the outset, there is no knowledge of chromosomal location. Determination of location is the aim of a mapping experiment, and yet assumed values are being used in ML methods prior to determining the location. Also, the restriction of fragment retention probabilities discards the experimentally observed frequencies of retention of individual markers. Despite these issues, ML methods form the basis of one of the most widely used software packages, RHMAP,[15,24] which has been used effectively in many mapping projects. Walter and Goodfellow[6] note that choice of different retention frequency models has little significant effect on the final maps generated by ML methods.

3.7 Methods for Determining Order

The methods described above are used to estimate distances between pairs of markers, but not the relative order of more than two markers. For N markers there are $N!/2$ possible orders, and the number of possibilities increases rapidly with the number of markers. Efficient means are needed for identifying the best order(s) from the vast number of possibilities.

One means of determining order, but with no estimate of distances between adjacent loci, or of the likelihood of the computed order, is to find the order which minimizes the obligate number of breaks. This can be seen in Figure 1. Looking down a column in the middle and right-hand panels, the number of obligate chromosome breaks implied by a particular order of markers is the number of times down a column when the hybrid type changes from present to absent or vice versa, since each such discontinuity must be due to a chromosomal break between the flanking markers. The number of breaks in the correct order in the middle panel is 89, and in the randomized order, 759. It therefore seemed natural to find an order which minimized the number of breaks, since a random order has more breaks than the true order. This method was used previously in genetic mapping[25] by permuting the order of markers to reduce the number of implied recombinants. Falk[26] and Boehnke et al.[15] describe the application of this method in RH mapping by permuting the linear order of markers. Thompson[25] observed that the method had the effect of moving spurious double recombinants to the ends of a linear map. A similar effect in the RH experiment is to move error-prone markers to the ends of the map. Since the number of different orders of N markers is large ($N!/2$), different methods of searching subsets of orders were suggested: stepwise locus ordering,[15] simulated annealing,[15,27] and branch-and-bound.[28] Only branch-and-bound is guaranteed to find the minimum. The statistical properties of the minimum breaks method were examined by Barrett.[29]

Another method of choosing likely marker orders from the vast number of possibilities was adopted in the program MultiMap/RADMAP.[30] This method uses CRIMAP[22] to calculate likelihoods for a given order, and a rule-based system using the AI language LISP to generate likely orders. The rules were constructed to replicate the process done manually by a human mapper, and were applied automatically to generate large numbers of likely orders. It increases the speed and efficiency of map construction. The best order chosen was the one with ML. Since the program reduced the time to generate maps, it also allowed exploration of different mapping approaches and heuristics used in map building. It was used in the construction of a map of human chromosome 13q containing 95 markers.[31]

A third method for determining order directly from a distance matrix using the techniques of distance geometry (DG) is discussed below (section 3.10).

3.8 Genetic Analysis Workshop 7

In 1992, the Genetic Analysis Workshop 7 focused on RH and somatic cell hybrid mapping of chromosome 21 and new computational methods.[32] This workshop demonstrated most of the methods currently used in the analysis of RH data, and provides a useful survey of the field. Nine groups analyzed the chromosome 21 RH data set using a variety of methods, mostly those recently developed by Boehnke et al.[15] Bishop and Crockford,[33] Boehnke,[34] and Weeks et al.[35] used different methods to find a marker order that minimized the number of obligate chromosome breaks. Bishop and Crockford[33] enumerated all possible orders of eight markers. Boehnke[34] used branch-and-bound to reduce the number of orders that need to be evaluated by eliminating groups of orders that had been shown to be suboptimal; Falk[36] used simulated annealing to the same end. Falk[36] also measured the coretention correlation (r) between all pairs of loci, and large values of the correlation indicated closeness of markers. The order of markers was permuted to maximize the sum of correlation between adjacent markers. The measure of distance was chosen to be $1 - r$. Weeks et al.[35] estimated the probabilities that pairs of markers be transferred to the hybrid on the same fragment. They then also iterated over different locus orders, using simulated annealing, to find the order that maximized these probabilities between adjacent markers.

Likelihood methods were also demonstrated, using the framework developed by Boehnke et al.[15] Chakravarti and Reefer[37] assumed that all markers were retained with equal frequency, and built locus orders one marker at a time, and obtained the same order as Cox et al.[5] Bishop and Crockford[33] used both equal retention and centromerically preferred retention, and found that distances were very similar for the two different models. Green used the likelihood method CRIMAP of Lander and Green[22] developed for the analysis of genetic mapping data, and obtained the same marker order as Cox et al.[5] Lawrence and Morton[38] used a multiple pairwise approach that had been used previously for genetic maps.[39] They also obtained Cox's marker order. Bayesian methods were used by Guerra et al.,[40] but it was found that the method was computationally very difficult, even for two or three loci.[32]

3.9 Hidden Markov Models

A novel application of the statistical models known as hidden Markov models (HMMs) was demonstrated

by Slonim et al.[41] HMMs were used to estimate the likelihood of a map, when there is some uncertainty about typing. Graph algorithms are used to find sparse but reliable initial maps. The method is resilient to typing error by assigning a priori false positive and negative rates, and allowing for such errors in the ML calculation. The method automatically detects markers that are likely to be error-prone.

3.10 Distance Methods

We adapted our previous method[42] for constructing genetic (meiotic) maps using DG to obtain maps from RH data.[12] This technique obtains coordinates from a measured distance matrix which gives distances on the derived map that optimally fit the observed distances. DG was developed in the field of nuclear magnetic resonance (NMR) to determine three-dimensional models of small proteins from observations of inter-proton distances obtained from NMR spectroscopy.[43–45] Applied to RH mapping, the procedure was as follows:

1. Obtain a full $N \times N$ distance matrix from the joint retention frequencies of all pairs of markers according to Equation (21), and their associated variance, Equation (23).
2. The distance matrix was first ''smoothed'' by replacing large imprecise distances with sums of smaller more precise distances. The variance estimate, Equation (23), was used as a measure of precision.
3. Obtain a ''metric matrix'' **G** from the smoothed distance matrix, which comprises the dot products of the vectors of each point to the origin[45] according to Equation (25)

$$g_{ij} = \frac{D_{i0}^2 + D_{j0}^2 - D_{ij}^2}{2} \tag{25}$$

where D_{i0}^2 is the squared distance of point i to the origin. This can be calculated without prior knowledge of the coordinates[43] according to Equation (26)

$$D_{i0}^2 = \frac{1}{N}\sum_{j=1}^{N} D_{ij}^2 - \frac{1}{N^2}\sum_{k>j=1}^{N} D_{jk}^2 \tag{26}$$

4. Coordinates are obtained for each of the points from the eigenvalues and eigenvectors of the metric matrix as Equation (27)

$$c_{ij} = \sqrt{\lambda_i} w_{ij} \tag{27}$$

where c_{ij} is the ith coordinate of the jth point, λ_i is the ith largest eigenvalue, and w_{ij} is the jth element of the corresponding eigenvector. Coordinates obtained in this way have been proved to be optimal[44] in the sense that the spatial configuration of points so obtained minimizes the rotation error against the original distance matrix.

The method was applied initially[42] to the chromosome 21 data,[5,7] and subsequently[12] to the RH data used to generate the human gene map.[46] It generates orders directly from the calculated coordinates in a method with complexity $O(N^3)$, i.e. the time taken for the computation to complete is proportional to N^3 where N is the number of markers being considered.

4 MAIN SOFTWARE AVAILABLE

Many of the methods described above have been incorporated into software packages that can either be downloaded from the Internet, or are implemented as methods on mapping World Wide Web (WWW) servers to which data can be submitted, and the results returned in a Web browser or by e-mail. The main packages available are listed below, with the methods that they use.

4.1 RHMAP

The minimum breaks method and the ML methods developed by Boehnke et al.[15] and further by Lange et al.,[24] have been incorporated into a package RHMAP. It is available at http://www.sph.umich.edu/group/statgen/software/.

4.2 RHMAPPER

RHMAPPER[41,47] is a software package for constructing RH maps, and was designed to map very large numbers of markers. It has other additional features: ML calculations using HMMs for analyzing diploid cells, such as those used in whole genomic mapping, and accommodation and detection of laboratory error. It is available at http://www-genome.wi.mit.edu/ftp/distribution/software/rhmapper/.

4.3 Z-RHMAPPER

Soderlund et al.[48] introduced modifications to RHMAPPER. The software is available at http://www.sanger.ac.uk/Users/cari/Zman.html.

4.4 SAMAPPER

Stewart et al.[49] used simulated annealing to order loci in the package SAMAPPER (http://www-shgc.stanford.edu/Mapping/SAMapper/). It first obtains lod scores between all pairs of markers. The sum of lod scores between adjacent markers is then maximized by permuting the linear

order of markers. The search through the $N!/2$ possible orders is directed by simulated annealing. Their model suggests that the solution with the maximum sum of lod scores is the most likely solution.

4.5 MultiMap/RADMAP

MultiMap/RADMAP[30] is located at http://linkage.rockefeller.edu/multimap/. It automates the generation of alternative but likely orders using the results of likelihood calculations at previous stages, using rules coded in the AI language LISP. The authors recommend its use for large-scale mapping projects (>20 markers), or for the construction of many smaller maps.

4.6 Distance Geometry Map

The distance methods developed for RH mapping[12,42] are available at http://www.oxmol.com/biolib/webmap.[50] There are three modes of use: (1) copy and paste RH data for a series of markers, which are mapped with respect to each other; (2) find the N nearest markers to a named marker, and construct a locally accurate map in the vicinity of the reference marker rather than a whole chromosome; (3) enter the RH data vector for a novel marker typed on a RH panel, retrieve the N nearest vectors to the marker vector from the specified RH panel, and map these markers relative to each other to build a locally accurate map including the novel marker.

5 PRACTICAL METHODS

Having reviewed the analytical processes involved in RH mapping, we now describe how data are obtained in the laboratory for subsequent analysis and determination of map location.

5.1 General

One common use of RH mapping is to determine the location of an unknown (previously unmapped) marker on the genome. This is typically done by typing the marker on a RH panel for its presence or absence in each cell in the panel, and comparing the retention pattern with those of previously typed markers to find the closest matching markers and hence chromosomal region. The other major use is to map a series of markers with respect to each other, which involves typing each marker against a panel and mapping them with respect to each other.

5.2 Obtaining a Radiation Hybrid Panel

RH panels are distributed by Research Genetics (http://www.resgen.com). There are three human panels (GB4, long range, low resolution; G3, mid range and resolution; TNG3, short range, high resolution), and single panels for mouse, rat, baboon, zebrafish and dog. For human mapping the choice of panel is determined by whether or not the approximate location of the marker is known previously. If not, it is best to use the long range, low resolution panel G4 to obtain an approximate location. If approximate location is known it is better to type on the higher resolution G3 or TNG4 panels, providing the marker density in the region is sufficiently high (see section 6).

5.3 Typing Markers on the Panel

''Typing'' a marker on a RH panel involves determining whether or not it is present in each of the individual component hybrids in the panel. Goss and Harris[1–3] used enzyme assays to determine presence or absence of genes. Southern blot hybridization was used in the later experiments of Cox et al.[5] Polymerase chain reaction (PCR) is now the preferred method, enabling small DNA samples to be detected in the hybrids. Several different protocols have been published on the WWW (Table 2). A typical RH typing gel from the Stanford Human Genome Center is shown in Figure 4. The presence of a marker in a hybrid is indicated by a PCR product which is visualized by agarose gel electrophoresis.

5.4 Finding Close Markers

The results of the PCR are entered into the computer either directly as a string of 0s (absence) or 1s (presence), or via a clickable ''typing frame'' such as the one in Figure 5. This second method of data entry reduces possible errors in data input. The retention pattern of the marker on the panel is compared against the typings of all other markers that have been typed previously on the panel. These are generally available in the public domain on various web servers. Close markers have similar patterns of retention on the panel. Several mapping servers are available on the WWW, to which individual marker typings, or sets of typings for more than one marker, can be submitted. The servers return lists of nearest neighboring markers. The nearest markers to ''marker_xyz'' from mouse are shown in Figure 6. The closest, RH74155, is on mouse chromosome 3.

5.5 The Map Location

The location of the new marker is then indicated by the known positions of the markers which it is close to. The

location of ''marker_xyz'' typed in Figure 5 is found to be close to a marker at 25.1 cM on the genetic map.

6 PROPERTIES OF RADIATION HYBRID PANELS

There are several RH panels available commercially, all of which differ in their means of construction, and therefore also in the properties they display. Here we discuss the variable properties of RH panels which must be considered for different mapping purposes.

6.1 Construction of Panels is under Experimental Control

Three parameters affect the results of a RH experiment: (1) the radiation dose used to construct the panel which determines the mean number of breaks in a unit physical interval (μ); (2) the density of typed markers in unit distance intervals (λ); (3) the number of hybrids in the panel, which determines the significance of any detected linkage and the precision of the distance estimates to other markers. The conditions of the RH experiment can be varied at will, and should be considered when constructing new hybrid panels, or choosing existing panels, for specific mapping projects. Specifically, if a whole-genome map of a previously unmapped organism is to be made and the number of markers is relatively low, then a lower dose should be used to construct the panel. If on the other hand a very high resolution map of a localized region of the genome characterized by a large number of unique markers is required, then a panel should be constructed with a very high dose, e.g. the human TNG3 panel.

6.2 Available Panels

Table 3 summarizes the main properties of the commercially available RH panels from Research Genetics

Figure 4 A typical RH typing gel from the Stanford Human Genome Center. Uniform resource locator: http://www-shgc.stanford.edu/Mapping/rh/procedure/image.html.

(http://www.resgen.com). The first panels to be constructed were for human (long-range G4,[51] medium-range G3,[49] short-range TNG3[52]). There are now panels available for mouse, rat, dog, zebrafish, and baboon.

6.3 Effect of Marker Retention Frequency

In order for a marker to be maximally informative about its coretention with another marker, it should be retained in 50% of the cells in the panel. The amount of information that a marker can provide about its linkage to other markers can be quantified by the statistical entropy, $H_{\mathrm{A}} = -\ {}_{X} p_x \log p_x$, $X \in \{\mathrm{A}, \mathrm{a}\}$. It is maximal when $p_{\mathrm{A}} = p_{\mathrm{a}} = 0.5$. The entropy is 0 for marker retention frequencies of 0 and 1.

6.4 Effect of Number of Hybrids on Resolution and Range

We define the resolution of a panel as the smallest breakage frequency that can be detected, and it is obtained when just one discordant hybrid is observed. As the number of hybrids in the panel is increased, the resolution increases. The range of a panel is the weakest linkage (largest value of the breakage frequency) that can be detected between adjacent markers with significance (e.g. with a lod score > 3). These values for simulated panels with the same radiation dose are summarized in Table 4. As the number of hybrids in the panel increases, so the resolution gets finer, and the range longer.

Figure 5 A ''typing frame'' originally developed for DG map at the BioLib site (http://www.oxmol.com/biolib/webmap). The user clicks the boxes which have been typed positive. ''Submit'' sends the data to the mapping server to find near neighbors.

6.5 Effect of Dose on Panel Range and Resolution

The X-ray dose used to fragment the donor chromosomes determines the size of the fragments generated: the higher the dose, the smaller the fragment size. Goss and Harris[1] determined empirically the relationship between rate of breakage and dose D as $D^{1.6}$. The exponent between 1 and 2 was interpreted as breakage involving one- and two-photon events. A compromise between two opposing properties of a panel must be struck when choosing the X-ray dose for construction of a particular panel.

Table 4 Predicted properties of RH panels with different numbers of hybrids. (Newell et al.[12])

Number of hybrids	Resolution			Range		
	θ	$Z(\theta)$	$D(R)$	θ	$Z(\theta)$	$D(R)$
10	0.156	2.01	0.170	0.40	1.24	0.51
20	0.080	4.30	0.084	0.40	3.83	0.51
50	0.033	11.0	0.034	0.48	3.63	0.65
100	0.017	22.0	0.017	0.64	3.50	1.02
200	0.009	43.8	0.009	0.76	3.16	1.43
500	0.004	109.2	0.004	0.85	3.17	1.88
1000	0.002	217.9	0.002	0.89	3.20	2.23

θ is the breakage frequency; $Z(\theta)$ is the lod score for the observed breakage frequency, where $Z(\theta) = -\log^{10}(P(\theta))$, and $P(\theta)$ is the probability that the observed value of chi-squared for a 2×2 (Equation 24) could have arisen by chance; $D(R)$ is the distance (in units of mean number of breaks) between a pair of markers corresponding to the breakage frequency θ, calculated from Equation (7), where $1 = 1$.

Figure 6 Results of the search for ''marker_xyz'' having the retention pattern on the mouse T51 panel shown in Figure 5, and boxed in red here. The nearest neighbors are ranked according to the number of type matches across the panel. The histogram to the right of the retention patterns is the lod score of linkage, calculated as the negative log of the χ^2 probability for the 2×2 joint retention frequency table. The chromosome to which the matching markers have been assigned is shown at the far right. The unknown marker is linked most strongly to RH74155 at 25.1 cM on chromosome 3 on the mouse genetic map with a lod score of 20.8.

A higher X-ray dose increases the potential resolution of the panel, since breaks occur closer to each other on average. Such panels can resolve markers that are closer to each other on a chromosome. But the significance of linkage over longer distances is severely reduced, since it is more likely that different markers segregate independently of each other, i.e. the range is shorter. This is manifest as ''holes'' in the map. Clusters of linked markers separated by holes cannot be ordered with respect to each other. This can be alleviated either by making an RH panel with a larger number of hybrids, increasing the number of observed concordant hybrids, or by typing a larger number of markers on the panel, thereby reducing the average distance between adjacent markers.

A lower dose reduces the resolution of the panel, since it is less likely that near markers will be separated by X-rays. However, longer distances between adjacent markers can be spanned.

An example of this is the G3 panel,[49] constructed with 8000 rad, which is useful for resolving close markers, but is not reliable for constructing whole genome maps, unless a very large number of markers is typed, and the GB4 panel,[51] made with a dose of 3000 rad, which is excellent for making maps of whole chromosomes, in which the distance between adjacent markers can be as large as 1 Mb. A new very high resolution panel, TNG4,[52] has been constructed with 50 000 rad, and will be used to construct ultra-high resolution maps of the human genome, possibly using single nucleotide polymorphisms as the mapping reagent.[53]

6.6 Effect of Marker Density on Significance of Linkage

The strength of a map can be defined as the average strength of linkage between adjacent (closest) markers on the map. This is determined by a combination of the mean number of breaks (μ) and the mean density of markers (λ) on the map. The mean density of breaks between adjacent markers is defined in terms of μ and λ as $\mu^* = \mu/\lambda$. The probability that adjacent markers are not disrupted by X-ray breaks is then $p_0 = e^{-\mu^*}$, and its complement is $\theta = 1 - e^{-\mu^*}$. Therefore, if the dose is high, or the density of markers is low, the linkage between adjacent markers is weaker and it is harder to build maps with confidence.

This was illustrated in the first human gene map,[46] which was constructed from the combined mapping on the GB4 and G3 panels. For the GB4 panel, $\mu_{GB4} = 0.04\,Mb^{-1}$, $\lambda_{GB4} = 0.36\,Mb^{-1}$, giving $\mu^*_{GB4} = 0.11$. The breakage frequency between adjacent markers on the GB4 panel is therefore $\theta = 1 - e^{-0.11} = 0.10$, which with an average retention frequency of 0.32 and 93 hybrids gives an average inter-marker lod score of 17.5. For the G3 panel, $\mu_{G3} = 0.27\,Mb^{-1}$, $\lambda_{G3} = 0.16\,Mb^{-1}$, giving $\mu^*_{G3} = 1.7$. The breakage frequency between adjacent markers on the G3 panel is therefore 0.82, with a lod score of 1.0. This very low average significance of linkage between adjacent markers on the G3 panels explains why the G3 map has many ''holes'', between which clusters of more strongly linked markers cannot be ordered with respect to each other. To avoid this problem on the even higher-resolution panel TNG3,[52] constructed with 50 000 rad, many new markers will have to be generated to maintain significant linkage across the panel with smaller chromosomal fragments.

7 APPLICATIONS OF RADIATION HYBRID MAPPING

The first applications of RH mapping were ordering of several markers in defined regions of the genome.[1–5] It was rapidly applied to data previously obtained from genetic studies of disease and of inheritance of polymorphic markers mapped by genetic linkage studies which had enabled construction of genetic maps of the human[9] and mouse[10] genomes.

7.1 Disease Gene Mapping

The technique of positional candidate cloning[54] involves first identifying an area implicated in disease, then identifying all genes that are thought to be located in a similar region. These genes are designated ''candidates'' due to their chromosomal location, and are categorized according to the likelihood that they might contribute to the disease phenotype. An example of the application of RH mapping to positional candidate cloning is the disease multiple endocrine neoplasia type 1, MEN-1.[55] The MEN-1 and bcl-1 disease loci were known to lie on chromosome 11. An RH panel was made from a hamster cell line fused with a hamster–human chromosome 11 hybrid cell line. Sixteen human genetic markers were mapped in this region, and ordered using the techniques of Cox et al.[5] This located the proto-oncogene SEA (S13 avian erythroblastosis oncogene homolog) between two other markers PYGM (muscle glycogen phosphorylase) and INT2 (murine mammary tumor virus integration site, v-int oncogene homolog) known to flank MEN-1; SEA was therefore designated a candidate gene for the MEN-1 locus. Many other disease regions identified by genetic studies have been mapped in a similar way: BRCA1,[56–58] neurofibromatosis type 2,[59] incontinentia pigmenti 1,[60] and Huntington's disease.[61]

7.2 Whole-genome Human Maps

In a similar way, the large number of genetic markers that had been mapped using meiotic techniques,[9,10] were subjected to the complementary technique of RH mapping. The markers had previously been shown to be unique and had been typed in naturally occurring populations. They were freely available for mapping on the new RH panels. Gyapay et al.[51] mapped 374 Genethon markers on the new GB4 panel, and found good agreement with the previous genetic maps. Stewart et al.[49] accomplished a similar task with 5994 markers generated at SHGC typed and mapped using the G3 panel. The largest map of sequence-tagged sites (STSs) contained 15 000 STSs.[62]

Earlier in the decade, it was proposed that sequencing of the entire human genome should be considered a practicality. Brenner[63] proposed that a reasonable intermediate stage should be first to sequence only those parts of the human genome that were actually expressed in tissue (1%), to maximize earlier the biologically functional information in the human genome. This proposal resulted in a vast effort to sequence all human expressed-sequence tags (ESTs).[64] It was soon apparent that the same underlying sequences were being measured independently by many different groups, and each many times. This prompted the construction of "UniGene",[46,65] whose aim was to cluster the individual EST sequences to the unique underlying gene that was being expressed. At the time, there were ~170 000 ESTs which were grouped into 49 625 clusters, of which 4563 (9%) corresponded to known genes. The current number of sequences in human UniGene is ~1.2 million, grouped in 75 000 clusters. Each gene is therefore represented by ~16 EST sequences on average, some genes being represented by many more.

Since most human genes are thought not to be polymorphic, it is not possible to map them using traditional genetic mapping techniques which detect different types of the same gene. RH mapping, in contrast, detects the presence or absence of sequences rather than sequence differences, and was therefore an obvious choice for mapping all human genes in a reasonable timeframe. An international consortium comprising 10 mapping centers was established,[66] with the intention of mapping all UniGene clusters. Representative sequences from each of the clusters (usually the longest) were distributed amongst the consortium members for typing on the G3 and GB4 panels. Map construction was coordinated at the Sanger Center, and the final maps were distributed from the NCBI web site. The first "gene map" of the human genome was published in 1996,[46] and showed the locations of more than 16 000 human genes. The latest release of this map[67] contains 30 000 genes.

Figure 7 Transcripts mapped to human chromosome 11, band 11p11.12, in genemap98.[67]

Figure 7 shows the locations of 46 markers on band 11p11.12 estimated to span 4.46 Mb of the total 3000 Mb comprising the human genome (0.15%). It contains 46 mapped markers,[67] 29 of which are associated with UniGene clusters, and 7 of these clusters are associated via their gene symbols to the database of human genetic diseases and disorders, OMIM.[68,69] OMIM provides links to MedLine (Table 2). The loci corresponding to the OMIM entries are: **133701**–exostoses, multiple, type II; EXT2; **162096**–neurite growth-promoting factor 2; NEGF2; **600623**–prostate cancer antimetastasis gene KAII, leukocyte surface antigen R2, SAR2; antigen CD82, suppressor of antigenicity 6, prostate, ST6; R2 leukocyte antigen; **600811**–DNA damage-binding protein 2, DDB2; **171650**–acid phosphatase of tissues. The map has recently been updated[70,71] and contains 40 000 UniGene clusters.

The genomic localization of a unique DNA sequence can therefore potentially be linked to data and literature relating to human disease, and can provide a rapid means of devising novel strategies for the alleviation

or elimination of the symptoms of disease. This is one of the hopes of the new science of ''pharmacogenomics''.

7.3 Mapping Other Organisms

Genetic mapping studies of organisms other than human both predate and lag human studies. They predate human studies for two reasons: (1) genetic selection has been practiced for thousands of years on agricultural species (plants and livestock) to increase yield; and (2) the genetic basis for inheritance of characteristics was established primarily in nonhuman species. The results of genetic studies conducted on ''model'' organisms such as mouse and rat has also generated many variant phenotypes that resemble human disease phenotypes. They lag human studies since most attention following the development of modern molecular biology has been towards understanding malfunctions or disease phenotypes in man. However, the large-scale application of these techniques in nonhuman species is rapidly gaining pace.

The mouse provides many model systems for the study of human disease, so a dense genetic map is of great value. An RH panel for the mouse (T31) was constructed in 1996[72] and enabled construction of the first genome-wide RH anchor map of a model organism[73] containing 271 STSs. Markers were located on average 8.8 Mb apart, and contained some gaps which could not be bridged using the RH panel. Clusters of strongly linked markers were therefore ordered with respect to each other by anchoring on the genetic map. Mapping of ESTs on the mouse genome to a similar density as the human is in progress.[74] The current genetic map, containing ~7000 genes, is too sparse to allow successful application of the positional candidate cloning approach. The higher density RH map will allow mapping of many more genes. Centers mapping the mouse genome are the Jackson Laboratories, the Whitehead Institute and the Wellcome Trust Mouse Genome Center (see Table 2).

Many genetic experiments have also been conducted on the rat, and the phenotypes are useful as model systems for the study of similar conditions in humans. A RH panel of rat has been constructed and a dense map containing 5255 markers was recently published.[75] Another rat mapping project,[76] coordinated at the Whitehead Institute, has currently mapped 4736 simple sequence length polymorphism markers. These new maps of rat have revealed large regions of similarity between the rat and mouse and human genomes, providing valuable data for comparative mapping between the organisms.

The zebrafish has become a useful model organism for the study of the early stages of development, due to the ease with which its phenotypes can be determined by microscopy. A zebrafish RH panel has been constructed[77,78] and is being used for mapping cloned genes and ESTs which are candidates for developmental mutations.[79] The RH map is being anchored to the genetic map.[80]

An RH panel containing the entire dog genome has been constructed[81,82] on which 552 markers have been mapped. The dog species comprises 300 breeds and therefore contains a vast amount of polymorphism, manifest in many different phenotypes, e.g. physical appearance, behavior, and pathology. It is therefore an excellent species in which to study the genetic basis of these traits. The aim is to integrate the RH map with the third generation linkage map through the 207 common markers.

RH panels have also been constructed for cat,[83] pig,[84,85] and cow.[86]

7.4 Integrating Data

One of the major problems remaining is to integrate the vast amount of new mapping data with the existing knowledge of the genes themselves, their products, their functions and pathology. This was highlighted already in 1996[87,88] as a current problem. Eight years previously, it had been suggested that map and sequence data should be linked by STSs.[89] One locus would be represented by one STSs which has one DNA sequence. Weissenbach and Bentolila[87] regret that this has not been adopted in practice. They identify many sources of the problem, one being the proliferation and growth of databases such as dbEST, dbSTS, UniGene and OMIM. The problem is particularly acute in mouse and rat mapping, where different data are stored at many different sites. Databases easily and rapidly lose synchronization. Weissenbach and Bentolila suggest that mapping information should be simultaneously submitted to all relevant databases via a standard form. This would also prevent unlinked duplications. A universally acceptable mechanism is not yet implemented. When it is, the potential of the RH technique for comparative mapping and functional genomics will be greatly increased.

8 CONCLUSIONS

RH mapping is now an efficient and fast means of locating unique DNA sequences on a genome, and many methods exist for analyzing results of new RH experiments. The underlying physical processes are assumed to be simple, and have been of enormous importance in the HGP, providing a framework on which to place the DNA sequences of clones covering the entire human genome. The RH technique is now indispensable in rapidly generating genome-wide maps of different species. It was used to generate the high-resolution framework on which

to locate the large stretches of human DNA which are being measured in the HGP. It is almost certain that after completion of the HGP, RH mapping will be similarly used in the sequencing of other large vertebrate genomes, particularly mouse and rat. The high-resolution mapping of these organisms is already under way. It is also likely that similar effort will be directed at determining the gross genomic structure of any other organism that is considered important. It is already active in genomes of agricultural importance. It is further possible that any of the ~1 000 000 species on the planet will at some stage become abnormally hostile or abnormally beneficial. In these cases, RH mapping is a tool that can be used to investigate such species and characterize them at the genomic level, giving better understanding of their biological properties and effects.

ACKNOWLEDGMENTS

I would like to thank colleagues at the Imperial Cancer Research Fund, London, UK, Glaxo Wellcome Medicines Research Centre, Stevenage, UK, Oxford Molecular, Oxford, UK, and the Aventis Cambridge Genomics Center, Cambridge, USA, for valuable and informative discussions of different aspects of this subject: Stephan Beck, Kathy Call, Tim Connolly, Rainer Fuchs, Amanda Jackson, Hans Lehrach, Andrew Lyall, Brian Packard, John Riley, and Phillipe Sanseau.

Restriction landmark genomic scanning (RLGS) is a method for the high-speed survey of the presence or absence of restriction landmarks throughout a genome. RLGS also provides for the measurement of the copy number of restriction landmarks based on the concept that restriction enzyme sites can serve as landmarks. RLGS employs direct end-labeling of the genomic DNA digested with a restriction enzyme and high-resolution, two-dimensional electrophoresis. Compared with the conventional technologies for detecting the genes, such as Southern blot analysis and polymerase chain reaction (PCR), RLGS has the following advantages even though it needs specially designed instruments: (1) high-speed scanning ability – thousands of restriction landmarks can be scanned simultaneously; (2) applicability to any organism – RLGS employs direct labeling of restriction enzyme sites, not a hybridization procedure; (3) a spot intensity that reflects the copy number of the restriction landmarks; and (4) the ability, by using a methylation-sensitive enzyme, to screen the methylated state of genomic DNA.

RLGS is a very useful system not only for genome mapping, but also in a variety of biological and medical fields, such as cancer research and the growth and development of various organisms throughout all stages of the life cycle. RLGS can also be applied for the visualization of mRNAs [restriction landmark cDNA scanning (RLCS)]. In one procedure, RLCS can scan the expression of several hundred mRNAs.

1 DEFINITIONS

Landmark: a locus or site to be visualized, distributed across genomes. A landmark can be utilized as a genetic marker, which should represent the physical condition, such as copy number, of its flanking region.

Restriction landmark: a landmark which can be recognized by a restriction enzyme.

RLGS: a method for visualizing restriction landmarks as spots on a two-dimensional profile. RLGS visualizes more than 2000 restriction landmarks in a genome in one procedure. RLGS has many applications, such as making a whole genome linkage map and scanning the amplified or deleted loci in cancer.

RLCS: a cDNA visualization system in which RLGS is applied to display many cDNA species as two-dimensional gel spots. The intensity of each RLCS spot reflects the expression level of each corresponding gene.

DNA methylation: in higher organisms, methylation of cytosine residues is often observed in genomes, and DNA methylation generally associates with the gene expression.

Restriction landmark genomic scanning for methylation (RLGS-M): a method for scanning genome-wide methylation conditions. RLGS-M can survey both endogenously imprinted genes and potentially expressed genes, based on the correlation of DNA methylation with gene expression.

2 INTRODUCTION

In recent decades, international genome projects have been making great progress toward the determination

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

of the sequence of genomic DNA and the full-length cDNA encoding its final protein products.[1–3] In terms of the analysis of the genomic structure, the full DNA sequence – including all information encoded by DNA other than DNA modification (methylation) – is the final goal. To achieve this, much effort has been devoted to the development of DNA sequencing technologies to facilitate sequencing speed. In fact, recent advances in these technologies should enable the entire genome-wide sequencing – or at least the rough sketching of the genomic sequence – to be completed within a few years, even for human, mouse and other higher organisms whose genome size exceeds 3×10^9 base pairs (bp). Once the genomic sequence and the full-length cDNA sequence have been determined, the diversity of genomes can then be analyzed by studying sequence variations, such as single nucleotide polymorphism (SNP).

The technologies for de novo mapping and sequencing of the genome are totally different from postsequencing technologies. In the initial sequencing project, the mapping and sequencing technologies should not require any pre-existing information concerning the genome-wide sequence. On the other hand, at the postsequencing stage, the existence of genome-wide sequencing information will allow us to design much faster and more accurate technologies to analyze the individual variations in a sequence which has already been determined. In other words, we can then use any region of the genomic DNA as a 'landmark', based on knowledge of the genome-wide sequence.

The concept of genomic scanning arose from the necessity to sketch out the framework of the genome, using appropriate technology to visualize landmarks distributed throughout the genome. In this context, a 'landmark' is defined as a locus or site to be visualized, distributed across genomes. However, different types of landmark are used for genomic scanning prior genome-wide sequencing. The landmarks used in the pregenome-wide sequencing stage (presequencing landmarks) should not require any a priori sequencing information. On the other hand, landmarks used subsequent to genome-wide sequencing (postsequencing landmarks) should be susceptible to much more rapid screening than those used in the presequencing stage, taking advantage of the fact that postsequencing technology can use landmarks already identified. Once the genomic sequence has been determined, oligonucleotides which hybridize at any given site on the genome and which amplify any region of the genome through PCR can be designed to single-base accuracy. In theory, oligonucleotide chips can be used to identify SNP at any site on the genome. However, even with the recent amazing improvements in sequencing technology, the sequencing of large genomes still requires enormous amounts of time, labor and financing, and at present the best that can be expected is that the human genome may be completely sequenced in the coming few years. Under the circumstances, with many genomes to be analyzed, a rapid genome scanning system for de novo mapping based on 'presequencing landmarks' remains essential, not only for mapping, but also for the sequencing itself.

The ideal landmark for genomic scanning should offer the following benefits: (1) robust landmark signals which can be detected under reproducible conditions; (2) high-speed (multiplex) scanning; (3) signals which facilitate measurement of landmark copy number; (4) simple procedures and robotization; (5) scanning field expandability; (6) applicability to any organism; and (7) exportability of both techniques and information to other laboratories. So far, three types of 'presequencing landmarks' have been used to scan the genome. The first, the DNA probe with unique sequence, was quantitatively and qualitatively visualized using the Southern blot method. Detection of landmarks results from the sequence-specific manner of DNA–DNA hybridization. PCR was developed as an alternative method for detecting a second sort of landmark. PCR is a technique for amplifying a region of several hundred base pairs, flanked by a pair of oligonucleotide primers. Here, too, the specificity of the signals depends on the specificity of hybridization of the primers to a unique genomic region.

Recently, our group introduced a new or third approach, termed the 'restriction landmark', in which each site recognized by a restriction enzyme can be utilized as a landmark. Based on this concept, we have developed a method of RLGS which can visualize restriction landmarks as spots on a two-dimensional profile.[4,5] This method employs (1) direct end-labeling of genomic DNA digested with a restriction enzyme and (2) high-resolution two-dimensional electrophoresis. As a method, it provides an alternative, multiplex approach to genomic analysis using robust landmarks, based on the strict specificity of sequence recognition of the restriction enzyme.

RLGS is a very important innovation for the following reasons. First, it provides us with a most powerful and speedy tool for genome-wide mapping for any organism.[6–8] RLGS can scan more than 2000 landmarks in a single procedure. Once DNA samples from the family tree of any organism have been prepared, all of the polymorphic spots can be used for very rapid genetic mapping. Even in sketching out the framework of a genome, a mapping approach based on presequence landmarks, such as restriction landmarks, is still generally much faster than genome-wide sequencing, and a map of these landmarks is very helpful for the genome-wide sequencing itself. Second, RLGS does not require any a priori sequence information, reducing the total cost of mapping. The

most salient characteristic of restriction landmarking is that the methylation state of the landmark can be reproducibly assayed if a methylation-sensitive enzyme is used as the landmarking enzyme. To scan the methylation state throughout the genome, RLGS is thus the most rapid method available. In particular, the methylation condition of CpG islands controlling the transcription of genes can be quickly screened using GC-rich restriction enzymes such as *Not*I as the landmarking enzyme.

To sum up, both pre- and postsequence landmarks are essential for genome mapping and scanning, complementing each other. Here, we describe the RLGS process which allows restriction landmarks to be surveyed throughout a genome, together with suggestions for its application.

3 GENERAL PRINCIPLES

3.1 Restriction Landmark Genomic Scanning

RLGS is based on a new approach to scanning efficiently and visibly many restriction enzyme sites on the entire genomic DNA. In essence, two issues must be resolved to achieve such scanning. The first is how to label specifically the particular restriction sites as landmarks without incurring nonspecific labeling. The second is how to detect through one procedure as many landmark loci as possible. Owing to the high complexity of genomic DNA in higher organisms, it has previously been considered difficult to achieve specific end-labeling at particular restriction sites and to detect the labeled fragments by conventional gel electrophoretic analysis. For example, when six-bp-recognizing enzymes were conventionally used as restriction enzymes to analyze the genomic DNA of higher organisms, it was very difficult to separate and detect the labeled restriction enzyme sites as discrete gel spots, because of the huge number of restriction enzyme sites and the nonspecific labeling of damaged sites such as nicks, gaps and/or double-stranded breaks in genomic DNA. However, these problems have been overcome by adopting new eight-bp-recognizing restriction enzymes known as 'rare-cutters' so as to give an appropriate number of DNA fragments for separation, in addition to new types of dideoxy nucleotide analogs to reduce nonspecific labeling. There has also been the development of a high-resolution two-dimensional electrophoresis system which enables us to detect simultaneously a multitude of loci as gel spots with enhanced sensitivity. For RLGS, it is essential, of course, to prepare genomic DNA of high quality. Average length and damage such as gaps and nicks are significant considerations. Since contamination by short fragments of less than 10 kbp in length results in increased background noise, the DNA must be prepared carefully without enzymatic degradation, especially at the lysis step at which various kinds of endonucleases leak from the lysosome. Treatment with proteinase K is effective in curbing such degradation in DNA preparation, but more care must be paid to avoiding enzymatic degradation by nuclease than to avoiding mechanical degradation such as shearing.

Figure 1 is a schematic representation of the principles and procedure of RLGS. The DNA is treated step by step as follows.

3.1.1 Blocking

When a fixed amount of genomic DNA is subjected to gel electrophoretic analysis, the copy number of the DNA decreases as the genome size increases. However, nonspecific labeling is independent of genome size. Hence the ratio of noise to meaningful signals increases with increased genome size. Such noise substantially hampers the detection of specific signals in the case of genome sizes in excess of 1×10^8 bp. Thus, damaged DNA sites such as nicks, gaps and/or double-stranded breaks must be blocked in advance to avoid nonspecific incorporation of the radioisotope. For this purpose, a blocking technique has been developed employing dideoxy nucleotide analogs such as dideoxy-[α-thio] nucleotides with one sulfur atom substituted for an oxygen atom (Figure 2). The incorporation of the analogs protects the damaged sites from elongation which would cause nonspecific labeling, as well as from 3′ exonuclease attack at the same sites in the labeling step. These analogs are incorporated enzymatically by a DNA polymerase such as DNA polymerase I.

3.1.2 Landmark Cleavage with Restriction Enzyme E_L

The sites for restriction enzyme E_L are isotopically labeled as landmarks. It is important to consider how many landmarks are desirable for the efficient detection of as many gel spots as possible. The appropriate number of restriction sites for the landmarks is around 3000 (each restriction site gives two landmarks). This means that restriction enzyme E_L must be chosen to give DNA fragments with an average length of 1 Mbp in the case of human and other mammalian genome DNA whose length is approximately 3×10^9 bp. Thus, enzymes that recognize eight-base or rare sequences are most convenient for use as restriction enzyme E_L. Table 1 lists representative restriction enzymes.

3.1.3 Labeling of Restriction Landmarks

Different labeling procedures are adopted depending on the nature of the cleaved sites generated by the restriction enzyme treatment. For a 5′-protruding end, a filling reaction of [α-^{32}P]deoxynucleotide is carried out

L: Site for restriction enzyme E_L (restriction landmark)

M: Site for restriction enzyme E_M

N: Site for restriction enzyme E_N

Figure 1 Schematic representation of the principles of RLGS using two-dimensional gel electrophoresis. ∗1 and ∗2 represent the distance from restriction landmark L (site for restriction enzyme E_L) to the nearest sites M for restriction enzyme E_M. y_1 and y_2 indicate the distance from the restriction landmarks L to the nearest sites N for restriction enzyme E_N. These end-labeled fragments appear as spots ∗1 and ∗2 in the two-dimensional gel electrophoresis profile.

with Sequenase® Version 2, whereas for a 3′-protruding (or blunt) end, labeling is done with terminal deoxynucleotidyl transferase (terminal transferase) which can add [α-^{32}P]dideoxynucleotides at the 3′ termini of DNA fragments.

3.1.4 Fragmentation with Restriction Enzyme E_M

Generally, for mammalian genomes, more than 3000 DNA fragments of 1 Mbp average length are generated by treatment with restriction enzyme E_L, even when the

Figure 2 Dideoxy nucleotide analog, dideoxynucleoside [α-thio] triphosphate, used for the blocking procedure.

Table 1 Restriction enzymes usable for landmark cleavage (E_L) and sensitive to mammalian genome methylation

5′^{Me}CG-sensitive enzyme		5′ Non-^{Me}CG-sensitive enzyme	
*Not*I	GCGGCCGC	*Pac*I	AATTAATT
*Sfi*I	GGCCNNNNNGGCC	*Swa*I	ATTTAAAT
*Fse*I	GGCCGGCC	*Sse*8387I	CCTGCAGG
*Csp*I	CGG(A/T)CCG	*Pme*I	GTTTAAAC
*Mlu*I	ACGCGT		
*Asc*I	GGCGCGCC		
*Bss*HII	GCGCGC		
*Cla*I	ATCGAT		

chosen enzyme is *Not*I, the eight-bp-recognizing enzyme known as 'rare-cutter'. In this case, the DNA fragments are too large to separate by gel electrophoresis. To overcome the problem, treatment with restriction enzyme E_M, whose recognition sites occur more frequently in the genome than landmark E_L sites, is adopted. Restriction enzyme E_M must be selected to give a suitable number of gel spots allowing the use of a high-resolution electrophoretic thin-layer gel with a range extending to more than 40 cm.

3.1.5 First Fractionation by Agarose Gel Electrophoresis

In high-resolution electrophoresis, the thickness of the first dimension (1st-D) agarose gel is important, because its resolution affects that of second dimension (2nd-D) electrophoresis. Either horizontal or vertical gels are suitable if the gel is thin or fine enough to separate more than 3000 landmarks electrophoretically.

3.1.6 Fragmentation of Labeled DNA with Restriction Enzyme E_N

The agarose gel strip or gel cylinder used in 1st-D electrophoresis is treated in situ with restriction enzyme E_N, whose sites appear even more frequently than restriction enzyme E_M sites. Usually four-bp-recognizing enzymes are used as restriction enzyme E_N, but six-bp-recognizing enzymes are also usable.

3.1.7 Second Fractionation by Polyacrylamide Gel Electrophoresis

The thickness of the second gel is determined by that of the first gel, as already noted. The first cylindrical gel or 'noodle' is connected to the 2nd-D polyacrylamide gel, which is also usable either horizontally or vertically. DNA fragments between 70 bp and 2 kbp are separable by this electrophoresis.

3.1.8 Autoradiography

The gel sheets are dried and autoradiographed.

3.1.9 Results

Figure 3 shows a representative result of RLGS, when *Not*I, *Eco*RV and *Hin*fI are used as restriction enzymes E_L, E_M and E_N. More than 2000 spots are clearly visible.

3.2 Restriction Landmark cDNA Scanning

RLGS is a powerful and efficient method for analyzing an entire genome.[9] It enables us to visualize simultaneously many loci as gel spots. RLGS has proved to be powerful in various applications such as genetic mapping, detection of

Figure 3 Typical RLGS profile of mouse liver DNA using *Not*I, *Eco*RV and *Hin*fI as restriction enzymes E_L, E_M and E_N, respectively. Approximate sizes are shown in kb.

methylatable loci including imprinted loci and detection of aberrated loci in cancer cells.

RLCS is a novel cDNA visualization system in which RLGS is applied to display many cDNA species as two-dimensional gel spots. The principle of RLCS is essentially the same as that of RLGS, with the cDNA cleaved by restriction enzymes being labeled isotopically at the restriction sites and separated by high-resolution two-dimensional gel electrophoresis, followed by autoradiography. The preparation of cDNA species of a uniform length for each mRNA species is crucial for RLCS, just as the quality of DNA is crucial for RLGS. For this purpose, a specially designed oligo(dT) anchor primer which facilitates anchoring to mRNA at the upstream end of the poly(A) tail, and easy recovery by its biotin residue at the 5′ end, is used for cDNA synthesis. The primer also carries multiple restriction enzyme sites such as *Not*I, *Nru*I, *Xba*I and *Spe*I. A representative primer is 3′-AMT15CCCGCCGGCGAGCGCTAGAT-CTTGATCAG-biotin (M = A, G or C). Alternatively, an anchor primer with G, C or T instead of A at the 3′ end is also usable. Figure 4(a) and (b) is a schematic representation of the principles and sequential procedures of RLCS.

cDNA synthesized using reverse transcriptase and the anchor primer is enzymatically blocked by 2′,3′-dideoxyribonucleoside triphosphate (ddNTP) to prevent nonspecific labeling in the labeling reaction (steps 1 and 2 in Figure 4a). The cDNA is then cleaved by the first restriction enzyme E_L whose sites (L) are successively labeled as landmarks (steps 3 and 4). An enzyme that generates protruding cohesive 5′ termini is recommended for use as restriction enzyme E_L because its restriction sites are easily radiolabeled by DNA polymerase I. Such

Figure 4 Schematic representation of the principles and procedure of RLCS. (a) Preparation of RLCS sample. The thin horizontal line and thick double horizontal lines indicate poly(A) RNA and double-stranded cDNA, respectively. (b) Separation of cDNA species by two-dimensional gel electrophoresis. cDNA fragments in RLCS samples (CS1, CS2 and CS3) are separated by two-dimensional gel electrophoresis and detected as spots CS1, CS2 and CS3, respectively.

an enzyme is also preferable for recovering target fragments from the gel spots when spot cloning is necessary. These labeled fragments are recovered using streptavidin-conjugated magnetic beads (step 5), and released from the beads by restriction enzyme *Not*I, whose site is included in the anchor primer (step 6). The recovered fragments, which must be uniform in length for individual cDNA species, are subjected to high-resolution two-dimensional gel electrophoresis as in the case of RLGS (Figure 4b). In practice, cDNA synthesis is carried out using several micrograms of poly(A)$^+$RNA and 1 μg of the anchor primer. Double-stranded cDNA (0.2–0.3 μg, 1000 bp

Figure 5 Representative RLCS patterns. Poly(A) RNAs were prepared from mouse liver (a), cerebral cortex (b) and cerebellum (c). For restriction enzyme cleavage both *Bam*HI and *Bgl*II were used together as enzyme E_L, and *Hin*fI was used as enzyme E_M.

average size) obtained from 1 μg of poly(A)$^+$RNA is usually treated with restriction enzyme E_L, followed by labeling, and subjected to 1st-D gel electrophoresis.

Figure 5(a–c) shows typical RLCS patterns resulting from gel electrophoresis of cDNA samples prepared from mouse liver and brain (cerebral cortex and cerebellum). Approximately 500 gel spots are detected for the liver, their pattern differing substantially from that of any brain region. More than 1000 gel spots are observed for the two brain regions (Figure 5b and c), their gel patterns being very similar but not identical. The differences in intensity have been confirmed (using conventional Northern analysis employing cloned spots as probes) to reflect the expression level of each transcript (Figure 6a and b).

Is this RLCS method sufficiently sensitive to detect even very rare mRNA species? As already described, in RLCS 0.2–0.3 μg of cDNA is applied to each gel. Since the average size of the cDNA is 1000 bp, the total copy number of the cDNA is calculated as $[(0.2–0.3) \times (10^{-6})/(660 \times 1000\,\text{bp})] \times (6 \times 10^{23}) = (1.8–2.7) \times 10^{11}$. If the population of very rare mRNA species corresponds to 0.0001% of total mRNA,[10] the cDNA copy number is calculated as $(1.8–2.7) \times 10^{11} \times 0.0001\% = (1.8–2.7) \times 10^5$. By comparison, in RLGS, 1 μg of genomic DNA, corresponding to 3×10^5 copies for mammalian genomes, is applied per gel, and is enough to detect a large number of gel spots. Even spots whose intensity is several times weaker than that of the major spot population are readily detectable. This means that even very rare mRNA species are detected by RLCS.

Figure 6 The intensities of the RLCS spots correlate with expression levels of the corresponding mRNA species. (a) Profiles of the cloned spots, indicated by arrowheads. [These RLCS profiles are magnified portions from patterns (b) and (c) in Figure 5.] (b) Northern analysis using cloned spot DNA fragments as probes. 2 μg of poly(A)$^+$RNA from the cerebral cortex (1) and cerebellum (2) were used for each lane. S1–S5 represent spots from which probes are made. Approximate size of each band is shown in kb.

Hence, RLCS is a sensitive quantitative method that enables us to visualize more than 1000 cDNA species at once. However, the display of even more cDNA species as gel spots requires enhancement of the technique.

Recently, RLCS has been further improved and refined as follows. (1) The display of an increased number of gel spots has been demonstrated by using more than two RLCS gels and different restriction enzymes. However, the appearance of redundant spots proved problematic (redundant spots are spots corresponding to the same gene but appearing in two or more loci). To overcome this problem, the combination and order of application of the restriction enzymes are being examined.[11] (2) Accurate priming of reverse transcription reactions using anchored oligo-dT primers has been examined under novel experimental conditions. Theoretically, cDNA species which have different 3′ end sequences flanking poly(A) tails could be separately displayed on the different gels by using two different kinds of anchor primers with MN at the 3′ end. Thus, cDNA having a GC sequence at the 3′ end just upstream from a poly(A) tail should appear only when a GC anchoring primer is used. However, this has proved problematic in practice, because mispriming of the anchor primers causes a single cDNA to be observed in two different 'windows'. To avoid mispriming, we successfully improved the results by performing the reverse transcriptase reaction at a higher temperature in the presence of trehalose and oligonucleotide blockers.[12] By applying these two modifications, many more cDNA species can be displayed.

4 PROTOCOLS

4.1 Introduction

RLGS analysis comprises several steps: DNA extraction, landmark labeling, two-dimensional electrophoresis, spot analysis and spot cloning as described in section 2. Here, we elaborate on several aspects of the RLGS technique.

4.1.1 Choice of Restriction Enzymes, E_L, E_M and E_N

With various combinations of restriction enzymes, e.g. *Bss*HII, *Eco*RV and *Hin*fI, or *Pac*I, *Bam*HI and *Hin*fI, RLGS can screen the physical conditions of the restriction landmarks of the entire genome. Here, we describe

Figure 7 Apparatus for (a) 1st-D and (b) 2nd-D electrophoresis. (Photo: Biocraft Inc. catalog.)

the protocol for the set *Not*I, *Pvu*II and *Pst*I for screening deletion, amplification and methylation of the landmarks in the mammalian genome. The *Not*I recognition sequence, GCGGCCGC, is known to be generally located in the CpG islands,[13] enabling us to screen efficiently amplification and deletion of potential transcriptional units, because almost all CpG islands generally locate in the upstream region of transcriptional units.[14] Furthermore, since *Not*I is one of the methylation-sensitive enzymes, methylation conditions can also be screened.

4.1.2 DNA Extraction, Landmark Labeling and Two-dimensional Electrophoresis

As described in section 2, all procedures are optimized for producing a high-resolution profile with low background noise.

4.1.3 Apparatus for Two-dimensional Electrophoresis

RLGS uses specially designed apparatus manufactured by Biocraft Inc. (Tokyo, Japan) for both 1st-D and 2nd-D gel electrophoresis (Figure 7a and b). In 1st-D gel electrophoresis, an agarose gel noodle serves as the medium. Figure 8(a) and (b) shows the Teflon® tube used in the procedure, encased within an outer glass tube to maintain its shape. About 50 cm of agarose gel and slow electrophoresis facilitate the very detailed resolution of DNA fragments. The electrophoretic tank for the 2nd-D acrylamide gel electrophoresis is designed so that four gels can be processed at once (Figure 9a–d) The required acrylamide gels can also be made in this same electrophoresis apparatus, obviating the need to transfer gels.

Figure 8 Schematic representation of 1st-D electrophoretic apparatus. (a) Overview. Nine 1st-D agarose disk gels can be subjected to electrophoresis in one run. The upper end of the tank serves as anode and the lower as cathode. (b) Holder for agarose gel noodle. The inner Teflon® tubing is encased in an outer glass support tube (60 cm length).

4.1.4 Spot Cloning

The method used to recover landmark spots on RLGS gels is essential for further studies such as identifying the genes that may be associated with the landmark sites and determining their functions. Target DNA fragments electro-eluted from an RLGS gel can be directly cloned by ligation with an appropriate cloning vector when the genomic DNA of microorganisms of relatively smaller genome size (10^6–10^7 bp) – such as *Staphylococcus aureus* – is subjected to the RLGS system.[15] However, in higher organisms like mice or humans,

Figure 9 (a) Assembly of glass plates in 2nd-D electrophoretic apparatus. Four gel spaces, each 1 mm wide, are separated by five glass plates. (b) Adding acrylamide gel through Teflon® tubing at one end of the apparatus. Three holes, which serve to pass the electrophoretic current during the run, are temporarily sealed with 3 M Scotch tape. (c) Side view of the attachment of 1st-D agarose gel noodles to the 2nd-D polyacrylamide gel. (d) Fully assembled 2nd-D electrophoretic apparatus. The Scotch tape has been removed for electrophoresis.

which have a larger genome size of 3×10^9 bp, less than 0.75 attomoles (7.5×10^{-19}) of target DNA fragments are available from an RLGS gel spot for each 1.5 μg of sample application, making it necessary to enrich the DNA fragments before cloning. In section 3.4 below, we introduce two methods for spot cloning, a PCR-mediated method and a restriction trapper-mediated method.

4.2 Preparation of Genomic DNA

It is important to isolate genomic DNA with as little damage as possible, because nicks and gaps cause nonspecific incorporation of radioisotopes in the labeling step, resulting in background noise. To avoid any damage, the critical technical point is to suppress DNase activity.

4.2.1 Materials and Reagents

Tris–EDTA (TE) [10 mM Tris-Cl, pH 7.5–1 mM ethylenediaminetetraacetic acid (EDTA)]; phenol–chloroform–isoamyl alcohol (PCI) (50 : 49 : 1), 0.1% 8-hydroxyquinoline, buffered with TE; lysis buffer (150 mM EDTA, 1% sodium dodecyl sulfate (SDS), 10 mM Tris-Cl, pH 8.0); proteinase K solution (Merck, Darmstadt, Germany) [10 mg mL^{-1}, dissolved in distilled water (DW)]; RNase A solution (Boehringer, Mannheim, Germany) (1 mg mL^{-1} dissolved in DW, boiled for 15 min for inactivation of DNase); mortar; pestle; dialysis tube.

4.2.2 DNA Preparation

The mortar, pestle, spatula and aluminum foil are prechilled in liquid nitrogen (LN_2). A 2-mL volume of lysis buffer and 0.5 g of the tissue are frozen in LN_2 and wrapped in aluminum foil, after which the frozen tissue is crushed with a hammer. The tissue pieces are transferred to the mortar and ground into powder with the pestle. The ground tissue powder is transferred to a 50-mL Falcon tube, to which is added 25 mL of lysis buffer and 150 μL of proteinase K solution. Quick but gentle stirring with the spatula gives a viscous sample. This mixture is incubated for 20 min at 55 °C and, after chilling on ice, 25 mL of PCI are added, followed by gentle stirring with a rotator (25 rpm) for 30 min. The sample is then centrifuged at 3000 rpm for 30 min and the resultant aqueous phase transferred to a new Falcon tube. This PCI extraction should be repeated more than twice. After PCI extraction, the aqueous phase is transferred to a dialysis tube and dialyzed overnight against TE. Following dialysis, the sample is transferred to a Falcon tube, to which is added 40 μL of RNase A solution, and then incubated for 2 h at 37 °C. At this stage, the volume of the sample is about 30 mL. The sample is now divided into two Falcon tubes (about 15 mL each), to each of which 35 mL of ethanol are added, and the two are gently rotated (15 rpm) for 30–60 min to precipitate the DNA. After precipitation, the precipitates are retrieved and

Figure 10 Quality checking of DNA by agarose electrophoresis. Eight samples of mouse genomic DNA, purified for RLGS, have been electrophoresed in 1% agarose gel. DNA fragments shorter than 20 kb are scarcely observed under ethidium bromide staining. M depicts lambda/*Hind*III DNA size marker.

transferred to an Eppendorf tube to which are added 300–500 μL of TE buffer (drying is not necessary) and then kept at 4 °C to dissolve the DNA. The concentration is adjusted to 1 mg mL^{-1}.

Genomic DNA over 200 kb long can be recovered using this protocol. For checking the quality of the DNA, an aliquot portion is subjected to electrophoresis in 1% agarose gel. DNA fragments shorter than 20 kb should scarcely be observed under ethidium bromide staining (Figure 10). If a smeared image of fragmented DNA is seen, the samples are significantly damaged and should not be used for RLGS analysis.

4.3 Labeling of Restriction Landmarks

The labeling protocol is designed so that all reactions can be performed sequentially in a single tube. Manipulation is very easy, involving only the adding of reagents and mixing.

4.3.1 Materials and Reagents

DNA polymerase I (Toyobo); deoxynucleoside [α-thio] triphosphates (dGTP[α]S, dCTP[α]S) (Toyobo); dideoxynucleoside triphosphates (ddGTP, ddATP, ddTTP, ddCTP [Toyobo]); [α-^{32}P]dGTP (3000 Ci $mmol^{-1}$) (Amersham); [α-^{32}P]dCTP (6000 Ci $mmol^{-1}$) (Amersham); *Not*I (Takara); *Pvu*II (Toyobo); *Pst*I (Takara); *Sca*I (Takara); bovine serum albumin (BSA) (Sigma fraction V); Triton X-100; Sequenase® Version 2.0 (USB, Cleveland, OH, USA); 10× high buffer (HB) [500 mM Tris-Cl (pH 7.4), 100 mM $MgCl_2$, 1 M NaCl, 10 mM dithiothreitol (DTT)]; 10× medium buffer (MB) [100 mM Tris-Cl (pH 7.5), 100 mM $MgCl_2$, 10 mM DTT, 500 mM NaCl]; 2.5× SH buffer (0.375 M NaCl, 0.25% Triton X-100, 0.25% BSA); pBSII solution [0.5 μg/8 μL pBluescript II (Stratagene, San Diego, CA, USA) in 1× HB]; pUC18 (0.5 μg μL^{-1} pUC18 in 1× MB); DTT.

4.3.2 Blocking of DNA

For blocking DNA, mix the following reagents:

DNA	10 μg
10× HB	1 μL
1 M DTT	0.1 μL
10 mM dGTP[α]S	0.4 μL
10 mM dCTP[α]S	0.2 μL
10 mM ddATP	0.4 μL
10 mM ddTTP	0.4 μL
DNA polymerase I	0.5 μL
DW	to 10 μL

Mix gently, but completely, with pipeting (since DNA solution is very viscous, solutions must be thoroughly mixed). Incubate for 20 min at 37 °C for digestion and for 30 min at 65 °C for inactivating DNA polymerase I. All solutions except the sample and DNA polymerase I can be premixed and stored at −20 °C for use as blocking buffer.

4.3.3 Landmark Cleavage

Mix the following reagents:

DNA sample (blocked)	10 μL
2.5× SH buffer	8 μL
*Not*I (10 U μL^{-1})	2 μL

Mix completely and incubate for 2 h at 37 °C for complete digestion. It is recommended that digestion be routinely checked for completion. For this purpose, transfer 2 μL of the mixture into another tube, add the control plasmid and incubate in parallel at 37 °C for 2 h.

DNA sample	2 μL
pBSII solution	8 μL

After incubation, electrophorese with 0.8% agarose gel. When digestion is complete, only two clear bands should be seen. Observation of a 2.9-kb band indicates that digestion is only partially complete (Figure 11).

4.3.4 Landmark Labeling

After digestion is complete, add the following reagents for labeling the *Not*I landmarks. (At restriction landmarks generated by *Not*I, a radioisotopic nucleotide is incorporated with DNA polymerase I. Sequenase®, one of the DNA polymerases, is better for suppressing background noise, because it lacks the 3′–5′ exonuclease activity.)

DNA sample (landmark-cleaved)	18 μL
1mM DTT	0.3 μL

Figure 11 Checking for complete digestion with enzymes E_L and E_M. The test plasmid, linearized pBSII (lane 1), is added to an aliquot part of the E_L (*Not*I) digestion samples, incubated in parallel with the samples, and then electrophoresed in 1% agarose gel. If digestion is complete, only two bands can be seen (lanes 2–7). pUC18 circular plasmid (lane 14) is used in a similar manner to check E_M (*Pvu*II) digestion. Only linearized plasmids of 2.7 kb length are observed in lanes 8–13.

[α-^{32}P]dCTP	1 μL
[α-^{32}P]dGTP	1 μL
Sequenase® Version 2.0 (13 U mL^{-1})	0.1 μL

Mix well by pipeting, and incubate for 30 min at 37 °C.

In the case of 3′ protruding and blunt ends, landmarks can be labeled with [α-^{32}P]ddNTP by terminal deoxy transferase.[4]

4.3.5 Digestion with Restriction Enzyme E_M

The second digestion is performed with *Pvu*II. Add the following reagents to the sample tube:

DNA sample (landmark-labeled)	20.4 μL
1 mM ddGTP	1 μL
1 mM ddCTP	1 μL
100 mM $MgCl_2$	1.2 μL
DW	4.4 μL
*Pvu*II (10 U mL^{-1})	2 μL

Mix gently but completely by pipeting and incubate for 1 h at 37 °C. All solutions except for the sample and *Pvu*II can be premixed and stored at −20 °C for use as the second digestion buffer. As in the case of landmark cleavage, use of an aliquot portion is recommended to check for complete *Pvu*II digestion. For the purpose, 2 μL of the mixture are transferred to another Eppendorf tube and the circular pUC18 control DNA is added, followed by incubation for 1 h at 37 °C (the same as for the sample) and then electrophoresis in 0.8% agarose.

Sample	2 μL
0.1 μg of pUC18 circular plasmid	8 μL

After incubation, the sample is subjected to electrophoresis in 0.8% agarose and checked for digestion bands. If the digestion is complete, only linearized plasmids of 2.7 kb can be observed (Figure 11).

4.3.6 Adjustment of Sample Concentration

A 2-μL volume of the labeled sample is placed in an Eppendorf tube, to which is added 100 μL of salmon sperm DNA solution and 100 μL of ice-cold 20% trichloroacetic acid (TCA). After incubation for 5 min on ice, the precipitate is collected by filtering the solution through a glass microfiber filter. The filter is washed with 9 mL of ice-cold 20% TCA and the radioactivity remaining on the filter is measured with a liquid scintillation counter. The concentration of the sample is then adjusted to 9000 cpm μL^{-1} by the addition of 6× loading dye[10] and the sample is stored until 1st-D electrophoresis at 4 °C.

4.4 Two-dimensional Gel Electrophoresis

4.4.1 Materials and Reagents

All apparatus for both 1st-D and 2nd-D electrophoresis (Figure 7a and b) are manufactured by Biocraft (Tokyo, Japan), including the electrophoretic tanks, 1st-D gel holder (the glass support tube) and the Teflon® tubing.

10× 1st-D buffer (dissolve 242 g of Tris, 109 g of sodium acetate trihydrate, 42 g of NaCl and 23.4 g of EDTA disodium salt in 1.8 L of H_2O and adjust the pH to 8.15 with acetic acid; adjust the volume to 2 L and send through a 0.2-μm filter or autoclave; the pH of the 1× buffer should be 8.0); 10× Tris–boric acid–EDTA (TBE) buffer (dissolve 1210 g of Tris, 770 g of boric acid and 75 g of EDTA disodium salt in H_2O and adjust to 20 L); dye solution (0.25% bromophenol blue (BPB), 0.25% xylenecyanol in TE without glycerol); 0.8% agarose gel solution [dissolve 0.8 g of SeaKem® GTG agarose (FMC Inc.) and 5 g of sucrose in 1× 1st-D buffer]; 5% 2nd-D acrylamide gel solution (dissolve 96.7 g of acrylamide, 3.3 g of methylenebisacrylamide, 1.3 g of ammonium persulfate and 200 mL of 10× TBE in DW and adjust to 2 L with DW; add 800 μL of N,N,N′,N′-tetramethylethylenediamine (TEMED) just before use to solidify the gel).

4.4.2 Preparation for First-dimensional Electrophoresis

Gel holders for the agarose gel noodles are made from Teflon® tubing and glass support tubes, as shown in Figure 12. The hard glass outer cover to the Teflon® tubing not only protects the fragile agarose gel from damage but also makes handling easier. Because the inside diameter of the glass tube is slightly larger than the outside diameter of the Teflon® tubing that will be inserted, one end of the glass tube must be beveled and narrowed by heating and shaping to tightly fix the Teflon® tubing. As shown in Figure 12, the top of the Teflon® tubing is cut at an angle of about 15°, passed through the glass support tube from the unbeveled end and then pulled out about 2 cm at the top using pliers. It

Figure 12 Preparation of Teflon® and glass gel holder for 1st-D gels.

is necessary to ensure that the upper part of the Teflon® tubing is stationary before it is trimmed to leave about 2 mm at the top and about 1 cm at the bottom. Next, the tip of a flanging tool is heated and the top of the tubing pushed on to the heated tip. After a few seconds, the tool is removed and the top of the tubing is pressed against a flat smooth surface such as a sheet of glass.

A 0.8% agarose gel is used to separate DNA fragments in 1st-D electrophoresis. As shown in Figure 13, the 0.8% agarose dissolved in the 1st-D buffer is gradually sucked up into the tube until it reaches a height of 59 cm, that is, about 1 cm from the top, using a syringe fitted with a three-way stopcock. The three-way stopcock is immediately closed and the tube left until the gel solidifies, after which the stopcock is opened and the syringe–stopcock unit carefully removed.

A 350-mL volume of 1× 1st-D buffer is added to the cathodal bottom of the tank and the gel holders are fitted into the anodal top, after which the tank is filled with another 250 mL of 1× 1st-D buffer. Nine samples can be run simultaneously on the described apparatus.

4.4.3 Preparation of Second-dimensional Acrylamide Gel

The 2nd-D electrophoretic tank is assembled as shown in Figure 9(a–d). After sealing the side holes with 3M Scotch tape, the 2nd-D acrylamide gel solution is poured through the side Teflon® tubing until it reaches the top of the glass plates. A 3-mL volume of 2-butanol is gently dropped on top of the gel, which is left to stand for about 2 h. Just before the 2nd-D electrophoresis, the 3M Scotch tape is peeled off and the 2-butanol washed out with 1× TBE.

Figure 13 Schematic representation of gel casting. Dissolved agarose is sucked up using a syringe fitted with a three-way stopcock.

4.4.4 Running of First-dimensional Gels

After the gel noodles have been left at room temperature for about 1 h, they are ready for a run. A 15-μL volume of the labeled sample (containing about 140 000 cpm of labeled DNA) is applied to the gel. Electrophoresis is carried out at a constant voltage of 180 V for about 14 h, at which time the BPB dye reaches 50 cm.

4.4.5 Extruding and In Situ Restriction Enzyme Digestion

When the electrophoresis is completed, the anodal tank buffer is removed with an aspirator and the gel holders are taken out. The gel noodles can be expelled from the holders using a 1-mL syringe with a cut-off yellow Eppendorf tip. The gel noodles are cut 3 cm from the end, at the 500 bp point, and marked with BPB dye solution (0.01%) so as to make it easy to work with them. The noodles (about 57 cm in length) are soaked in 50-mL Falcon tubes containing 40 mL of 1× HB (Figure 14a and b) for 10 min. The buffer is changed and the noodles are soaked again for 10 min to reach complete equilibrium.

Digestion is carried out in situ in the Teflon® tubing. For this purpose, the equilibrated gel noodles are sucked up into the tubing, whose internal diameter is slightly bigger than that of the noodles (Figure 15a–c). After

Figure 14 Dialysis of 1st-D agarose gel noodle.

removal of all traces of the buffer, the tubing is filled with *Pst*I solution (1500 units *Pst*I in 1500 μL of 1× HB), and the tubing looped, with one end connected to the other (Figure 16). The looped, Teflon® tubing-enclosed gels are incubated for 2 h at 37 °C.

4.4.6 Running Second-dimensional Gels

After digestion for 2 h with *Pst*I, the gel noodles are expelled from the tubing into 50-mL Falcon tubes containing 40 mL of 1× TBE buffer. After 10 min of equilibration, the noodles are transferred into the glass slits of the 2nd-D electrophoresis apparatus as shown

Figure 15 Method for sucking up a 1st-D gel noodle into the Teflon® digestion tube.

Figure 16 Schematic representation of the sealing of a digestion tube. The sealed tube is incubated for 2 h for complete digestion.

in Figure 17(a) and (b). The space between the agarose and acrylamide gels is filled with 0.8% SeaKem® agarose in 1× TBE containing 0.05% BPB. After the overlaid agarose has solidified, both reservoirs are filled with 1× TBE and electrophoresis carried out at 150 V for about 24 h, at which time the tracking dye BPB will have reached the end of the gels.

4.4.7 Autoradiography

The gels are dried and autoradiographed, usually for 3 days, using Kodak X-AR film.

4.4.8 Restriction Landmark Genomic Scanning Profile

A representative result is shown in Figure 18. In this particular autoradiogram, more than 3000 spots can be separately distinguished.

4.5 Methods for Spot Cloning

4.5.1 Polymerase Chain Reaction-mediated Method

The principles behind the method are illustrated in Figure 19(a) and (b). The method consists of PCR amplification of adapter-ligated spot DNA fragments without the exclusion of similar-sized co-localized DNA fragments, following selective ligation with the *Not*I–dT vector. It can be expected that the similar-sized DNA fragments are present in abundance and therefore will work well as DNA carriers to prevent loss of the target spot DNA through the cloning step. The method is highly advantageous when the total DNA sample prepared for cloning is limited, as only a few micrograms of DNA in all is sufficient for cloning. This method is applicable to any spot DNA derived through RLGS using different sets of restriction enzymes for analysis, simply by changing the adapters, PCR primers and vectors for the subcloning. The method is also applicable to RLCS spot cloning.

4.5.1.1 Apparatus and Reagents *E. coli* DNA ligase (Takara); 10× ligation buffer for *E. coli* DNA ligase [300 mM Tris-Cl (pH 8.0), 40 mM $MgCl_2$, 100 mM $(NH_4)_2SO_4$, 12 mM EDTA, 1 mM NAD, 0.05% BSA]; spin column (Chroma Spin-100™; Clontech); NACS™ column (BRL); 10 μM *Not*I and *Hin*fI adapters (preannealed double-stranded oligonucleotides; 5′-ACGCCAGGGTTTTCCCAGTCACGACGC-3′ and 5′-pGGCCGCGTCGTGACTGGGAAAACCCTGGCGT-3′ for *Not*I site and 5′-pANTCTGTACTGCACCAGCAAATCC-3′ and 5′-GGATTTGCTGGTGCAGTACAG-3′ for *Hin*fI site); forward primer P77 (10 μM; 5′-AGGGTTTTCCCAGTCACGACGCGG-3′); reverse primer Ad2-2 (10 μM; 5′-pTTGCTGGTGCAGTACAGANTC-3′); *Taq* DNA

Figure 17 Schematic view of connection of 1st-D gel noodle to 2nd-D acrylamide gel. After laying the agarose gel noodle in one of the glass grooves, dissolved agarose (kept at 60 °C) is injected between the noodle and the acrylamide gel using a 5-mL syringe. Damage to the acrylamide gel surface by the syringe needle must be avoided.

polymerase (Takara); 10× PCR buffer [100 mM Tris-Cl (pH 8.3), 500 mM KCl, 15 mM $MgCl_2$]; dNTP mixture (2.5 mM each of dATP, dCTP, dGTP and dTTP); 50 ng μL^{-1} *Not*I–dT vector (a linearized dephosphorylated plasmid vector with both a *Not*I terminus and 3′-dT protruding terminus); linearly polymerized acrylamide (1% solution); 10× HB; 500 mM Tris-Cl (pH 7.4); T4 DNA ligase (Takara); 10× buffer for T4 DNA ligase [500 mM Tris-Cl (pH 7.5), 100 mM $MgCl_2$, 100 mM DTT, 10 mM ATP, 0.1% BSA]; 50% PEG6000.

Figure 18 RLGS profile of rat brain tissue. *Not*I, *Pvu*II and *Pst*I were used as E_L, E_M and E_N, respectively.

4.5.1.2 Procedures For the basic operations, such as electroelution, PCI extraction, ethanol precipitation, enzyme treatment and PCR reaction, see the general protocol books.[10] The restriction enzymes *Not*I, *Bam*HI and *Hin*fI are used in this experiment as RLGS restriction enzymes E_L, E_M and E_N, respectively. A 1-μg amount of the sample to be cloned is mixed with the same quantity of the end-labeled sample and subjected to the RLGS procedure. Following autoradiography, the target spots are cut out and their DNA fragments electroeluted and extracted with PCI, followed by ethanol precipitation using 10 μg of linearly polymerized acrylamide as a carrier, and then dissolved in 3 μL of TE.

A third of each DNA fragment is ligated overnight at 16 °C with *Not*I and *Hin*fI adapters.

DNA solution	1 μL
10× buffer for *E. coli* DNA ligase	0.5 μL
Adapter for *Not*I	0.5 μL
Adapter for *Hin*fI	0.5 μL
E. coli DNA ligase	1 μL (30 U)
DW	1.5 μL

After incubation, the ligation mixture is diluted to 40 μL and subjected to a spin column, after which the eluate is PCR-amplified through 30 cycles using the primers P77 and Ad2-2 as follows:

DNA solution (adapter-ligated)	37.5 μL
dNTP mix	5 μL
10× PCR buffer	5 μL
P77 primer	1 μL
Ad2-2 primer	1 μL
Taq DNA polymerase	0.5 μL

Figure 19 Schematic representation of PCR-mediated method of RLGS spot cloning.

The conditions for PCR amplification are 94 °C for 1 min, 60 °C for 1.5 min and 72 °C for 2 min. The PCR products are directly applied to the polyacrylamide gel electrophoresis and stained with ethidium bromide. The amplified bands are cut out and electroeluted, followed by purification through an NACS™ column. After ethanol precipitation, the resultant DNA is suspended in 10 μL of TE.

The amplified DNA is kinated and digested with *Not*I as follows:

DNA solution (amplified)	10 μL
10× kination buffer	5 μL
100 mM ATP	1 μL
DW	30 μL
T4 DNA polynucleotide kinase	4 μL

After incubation for 60 min at 37 °C, the DNA is extracted with PCI, precipitated with ethanol and suspended in 5 μL of TE, followed by *Not*I digestion.

DNA solution (kinated)	5 μL
10× HB	1 μL
*Not*I	1 μL (10 U)
DW	3 μL

Following *Not*I incubation for 60 min at 37 °C, the DNA is again extracted once with PCI, condensed through ethanol precipitation and suspended in 3.5 μL of TE. The resultant *Not*I-digested DNA is then ligated with *Not*I–dT vector:

DNA solution (*Not*I-digested)	3.5 μL
*Not*I–dT vector	2 μL
10× buffer for T4 DNA ligase	1 μL
T4 DNA ligase	1 μL (350 U μL^{-1})
50% PEG6000	1 μL
DW	1.4 μL

The product is incubated overnight at 16 °C and transformed into the appropriate *E. coli*, ex HB101.

4.5.1.3 Results We have succeeded in cloning much target spot DNA by the PCR-mediated method.[9,11,16,17] Almost 70% of the target DNA fragments have been successfully cloned. One of the disadvantages of the method is that it proved impossible to clone spot DNA fragments of more than 1000 bp in size. This may have been due to inefficient amplification of the target DNA fragments by PCR reaction. Nonetheless, the method has also been applied to cloning the spots from the RLCS system. Several target DNA fragments (genes) have already been cloned.

4.5.2 Restriction Trapper-mediated Method

The principles behind enrichment of target DNA fragments using a restriction trapper are illustrated in Figure 20. The restriction trapper, the key material for this process, consists of a hairpin-looped oligolinker covalently linked to the surface of latex beads (Figures 21 and 22). The method is based on purification of the target

Figure 20 Procedure for RLGS spot cloning with restriction trapper mediation. The presence of many unlabeled invisible fragments in the target spot of conventional RLGS gels prevents specific cloning. Eluting DNA fragments from the RLGS gel with restriction trapper purifies the DNA, which can then be cloned.

Figure 21 Structure of the restriction trapper for *Not*I fragments. A 36-base oligonucleotide is covalently linked to the surface of latex beads via a 10-base cytosine stretch. This oligonucleotide carries the *Not*I protruding end.

DNA fragments by the restriction trapper through ligation at their restriction landmark sites. Purified target DNA fragments sufficient for cloning can be obtained by increasing the initial amount of genomic DNA. It is therefore necessary to prepare several hundred micrograms of the genomic DNA and the rather specialized

Figure 22 Principles behind the purification of a target DNA fragment with restriction trapper.

restriction trapper. The method is nevertheless useful because (1) the spot DNA fragments are evenly enriched with restriction trapper, independent of fragment size, and (2) DNAs of many spots can be enriched and cloned simultaneously.

4.5.2.1 Apparatus and Reagents 10× HB [500 mM Tris-Cl (pH 7.4), 100 mM $MgCl_2$, 1 M NaCl, 10 mM DTT]; 0.1% BSA; 0.1% Triton X-100; 10× low buffer (LB) [100 mM Tris-Cl (pH 7.5), 100 mM $MgCl_2$, 10 mM DTT]; *Not*I restriction trapper, pre-washed once with TE and adjusted to 5% solution with TE (Gene Trapper R-*Not*I; Japan Synthetic Rubber); T4 DNA ligase (Takara); 10× buffer for T4 DNA ligase [500 mM Tris-Cl (pH 7.5), 100 mM ATP, 50% PEG6000]; 10× MB [100 mM Tris-Cl (pH 7.5), $MgCl_2$, 10 mM DTT, 500 mM NaCl]; 3000 Ci mmol^{-1} [α-^{32}P]dGTP; 6000 Ci mmol^{-1} [α-^{32}P]dCTP; Sequenase® Version 2.0

4.5.2.2 Procedures The restriction enzymes *Not*I, *Pvu*II and *Pst*I are used in this experiment as RLGS restriction enzymes E_L, E_M and E_N, respectively. A 1-mg

amount of genomic DNA is prepared (10 reactions, each of 100 μg) and completely digested with *Not*I and *Pvu*II.

DNA	100 μg
10× HB	20 μL
0.1% BSA	20 μL
0.1% Triton X-100	20 μL
*Not*I (8 U μL^{-1})	10 μL
DW	to 200 μL

The *Not*I-digested DNA is incubated for 2 h at 37 °C and then further digested by *Pvu*II by addition of the following agents:

DNA (*Not*I-digested)	200 μL
10× LB	20 μL
*Pvu*II (12 U μL^{-1})	10 μL
DW	170 μL

The reaction mixture is incubated for 2 h at 37 °C, extracted with PCI followed by ethanol precipitation, and dissolved in 50 μL of TE.

Ligation to the restriction trapper and purification are then carried out.

DNA solution (*Not*I–*Pvu*II-digested)	50 μL
*Not*I restriction trapper	20 μL
10× buffer for T4 DNA ligase	15 μL
100 mM ATP	2 μL
50% PEG6000	30 μL
T4 DNA ligase (350 U μL^{-1})	4 μL
DW	14 μL

The mixture is incubated for 2 h at 18 °C with occasional mixing. After inactivation of the ligase at 65 °C for 15 min, the restriction trapper is recovered by centrifugation at 15 000 *g* for 5 min followed by washing with TE. The trapper is then treated with *Pvu*II.

DNA (restriction trapper)	
10× LB	45 μL
*Pvu*II (12 U μL^{-1})	10 μL
DW	395 μL

After incubation for 1 h and washing twice with TE, the trapper is then treated with *Not*I.

DNA (restriction trapper)	
10× HB	10 μL
DW	60 μL
0.1% BSA	10 μL
0.1% Triton X-100	10 μL
*Not*I (10 U μL^{-1})	10 μL

The mixture is incubated for 2 h, at 37 °C, mixing every 30 min. After centrifugation, the target DNA fragments (*Not*I–*Pvu*II fragments) released from the trapper in supernatant are extracted with PCI, precipitated with ethanol and dissolved in 16 μL of TE. A small portion of the DNA fragments purified by the above method is end-labeled in the presence of [α-^{32}P]dGTP and [α-^{32}P]dCTP with Sequenase® Version 2.0.

DNA (*Not*I–*Pvu*II fragments)	3 μL
10× MB	1 μL
[α-^{32}P]dGTP	1 μL
[α-^{32}P]dCTP	1 μL
Sequenase® Version 2.0	1 μL
DW	3 μL

The mixture is incubated for 30 min at 37 °C.

The now radiolabeled DNA fragments are mixed with the remaining unlabeled DNA fragments and the whole is subjected to RLGS. After autoradiography, the DNA fragments in the target spots are recovered by electroelution, ligated with *Not*I–*Pst*I-cleaved plasmid vector and transformed into appropriate *E. coli* by the conventional method.

4.5.2.3 Results Using this restriction trapper-mediated method, several target DNA fragments have been successfully cloned from RLGS gel spots.[18–22]

5 APPLICATION OF RESTRICTION LANDMARK GENOMIC SCANNING

5.1 Potential Applications

RLGS, utilizing the concept of restriction landmarks, has various potential applications in biological research. In general, two major categories of application can be listed, the first being scanning of copy numbers of restriction landmarks across an entire genome. Based on genetic polymorphism or sequence variations between individuals at the restriction landmarks, the entire genome map can be rapidly constructed by high-throughput RLGS Version 1.8.[6–8,22–25] Furthermore, since RLGS needs no DNA probes or STS primers for detecting polymorphisms, a genetic map of any organism, e.g. the Syrian hamster, can be determined.[8] These genetic maps facilitate the analysis of positional cloning of genes responsible for genetic diseases.[26,27]

The second category of application is scanning of genome-wide methylation conditions, so as to survey both endogenously imprinted genes and potentially expressed genes, based on the correlation of methylation with gene expression. This method of scanning for methylation is named 'RLGS for methylation' (RLGS-M). RLGS-M is very powerful, because more than 2000 loci can be surveyed for their methylation status in a

single procedure. Using this approach, our group has already found and reported some imprinted genes in mice.[21,28,29] By way of illustration, in the next section we describe the application of RLGS-M to the scanning of methylation status associated with liver cancer in mice.

5.2 Application of Restriction Landmark Genomic Scanning to Cancer Research

5.2.1 Scanning Methylation State with Restriction Landmark Genomic Scanning Using Methylation-sensitive Endonuclease

Restriction landmark sites across an entire genome can be visualized and screened using RLGS techniques. If methylation-sensitive endonucleases are used for landmark cleavage, the appearance of RLGS spots varies depending on the methylation status of the landmark sites. When a landmark site is methylated and thus resistant to digestion, the corresponding RLGS spot disappears. Hence the RLGS technique is applicable to the scanning of the methylation state of landmark sites. We have named this approach 'RLGS for methylation' (RLGS-M) and have used it to screen for methylated loci/genes[28,30] which could contribute to tumorigenesis.

In RLGS-M analysis, the intensity of a spot reflects the copy number of a corresponding landmark site, because the number of end-labeled molecules at landmark cleavage sites corresponds to the level of incorporated radioactivity (Figure 23). Uniform levels of spot intensity are observed in diploid tissues; this is consistent with the cleavage and end-labeling of both alleles for most landmark sites. However, when methylation-sensitive enzymes are used to identify the landmark cleavage sites, the spots are reduced to half- or zero-intensity, respectively, when one or both of the alleles are methylated (Figure 23). GC-rich enzymes such as *Not*I (GCGGCCGC) or *Bss*HII (GCGCGC) cleave sequences that tend to be located on CpG islands.[31] It has been estimated that approximately 89% of *Not*I sites and 74% of *Bss*HII sites are on CpG islands. Hence the methylation status of CpG islands[13,32] can be evaluated using *Not*I or *Bss*HII to identify landmarks. Moreover, since methylation has been correlated with gene expression, it has been possible to screen *Not*I and *Bss*HII sites for allele-specific patterns of methylation.

Figure 23 Principle of RLGS-M analysis to detect changes in methylation pattern in tumor DNAs. Spots 1 and 2 are C57BL/6 (B) specific, whereas spots 3 and 4 represent *Mus spretus* (S)-specific polymorphic alleles at the same loci. Empty circles indicate nonpolymorphic spots. In the F1 normal tissue of a cross between B and S (BSF1), polymorphic spots appear as haploid (half-intensity) spots and nonpolymorphic spots appear as diploid (full-intensity) spots. In tumor DNA from a BSF1 animal, DNA methylation at the landmark site of a polymorphic spot (B-specific spot 1) leads to the absence of the spot in the RLGS profile. Spot loss can be analyzed by a comparison of normal and tumor RLGS DNA profiles. [Reproduced from Akama et al.[30] by permission of the American Association for Cancer Research, Inc.]

5.2.2 Overview of Cancer

Tumorigenesis is a multi-step process involving both epigenetic and genetic alterations.[31,33] The identification of genetic mutations, which cause either increased functioning of proto-oncogenes or loss of functions of tumor suppressor genes, provided a rationale for understanding tumorigenesis. However, the mutation of a single proto-oncogene or tumor suppressor gene is usually not sufficient in itself to cause neoplastic growth, tumor progression depending on secondary events. The genetic targets for these secondary events could be expected to depend on the initiating event and also developmental and tissue-specific factors regulating cell proliferation which arise during cell proliferation. Additional 'steps' involving angiogenesis, invasive growth and metastasis generate more serious life-threatening[34] disease. Although the 'cast of characters' involved in these processes is large and growing, our understanding of them is complicated by the large number of genes involved, developmental and tissue-specific differences in growth regulation and the stochastic nature of the process.

Alterations in DNA methylation are consistently found associated with tumorigenesis and may play a variety of roles in tumor progression.[35,36] In general, tumor DNA is hypomethylated, while hypomethylation is associated with increased gene expression. Several proto-oncogenes have been shown to be hypomethylated in tumors.[35,37] By contrast, regional hypermethylation may promote tumorigenesis by silencing expression of tumor suppressor genes, the genes necessary for differentiation and cessation of growth,[35,38,39] or hormone receptors which have a role in the growth or properties of the tumor.[40,41] In addition, increased

methylation may be mutagenic since 5′-methylcytosine can deaminate spontaneously to T, resulting in a C to T transition.[35,36] Results indicating that expression of an exogenous DNA methyltransferase can induce transformation of NIH/3T3 cells supports the contention that DNA hypermethylation plays an important role in tumor progression.[42]

In recent years, a number of new technologies have been developed which can be used for rapidly screening tumors for genetic alteration on a genome-wide basis. Most of these methods depend on nucleic acid hybridization to detect gain or loss of DNA sequences. These methods include comparative genomic hybridization,[43] representational difference analysis,[44] PCR analysis of simple sequence length polymorphisms (SSLP)[45] and RLGS.[5] Although each method has its advantages and disadvantages, the RLGS method is potentially powerful in terms of the number of loci that it is capable of screening simultaneously, its facilitation of direct cloning of genetic regions which are altered during tumorigenesis[20] and its ability to detect and localize regional hypermethylation or hypomethylation changes.

Figure 24 RLGS-M profile of normal BSF1 liver DNA produced by the enzyme combination *Not*I, *Pvu*II and *Pst*I. (a) Fourteen spots showing loss (methylation) in more than 75% of 30 hepatoma samples are indicated by arrows. (b) A magnified section of the normal RLGS DNA profile containing spot S238 – indicated by the arrow – (1) is compared with the same part from a profile of tumor DNA (2). [Reproduced from Akama et al.[30] by permission of the American Association for Cancer Research, Inc.]

5.2.3 *Analysis of Mouse Liver Tumors for Alterations in DNA Methylation Status Using Restriction Landmark Genomic Scanning Using Methylation-sensitive Endonuclease*

The principles by which RLGS-M analysis is used to detect DNA methylation status is shown in Figure 23 through a schematic representation of the RLGS patterns of normal tissues from parents and F1 progeny, as well as of F1 tumor tissue. Polymorphic paternal- (S) and maternal- (B) specific genes are transmitted to F1 progeny by Mendelian inheritance, and show up under general RLGS analysis as half-intensity spots. Using a methylation-sensitive enzyme, such as *Not*I, we can detect alterations of the DNA methylation status at such sites throughout the genome. When comparing tumor DNA relative to control DNA, methylation of a *Not*I site in the tumor DNA results in spot loss, whereas demethylation of a *Not*I site results in the appearance of a new spot. An example of the disappearance of the spot due to methylation in a tumor is illustrated (see Figures 23 and 24b). In order to help characterize the alterations of methylation status in tumor DNA, we utilized interspecific F1 hybrid, strain-specific haploid spots whose chromosomal locations are known through genetic analysis.[24] The 575 loci/spots (340 B- and 235 S-specific) were mapped by RLGS analysis (using *Not*I, *Pvu*II and *Pst*I) of BSS backcross progeny.[24] Using the new RLGS Version 1.8,[7,46] 507 of the mapped spots provided useful information for the rapid analysis and localization of genomic alterations such as changes in methylation at landmark sites.

RLGS-M analysis was performed on 30 liver tumor DNA samples from 14 interspecific F1 hybrid mice offspring of S and a transgenic B57BL/6 (B6) line containing the SV40 T antigen early region connected to a mouse major urinary protein (MUP) enhancer/promoter.[30] In cancer tissues, changes in the intensity of the RLGS spots may reflect DNA loss, rearrangement or amplification, and also alterations in methylation as described above. Random alterations would be expected to occur due to genomic instability in the course of tumorigenesis, but some alterations may be primary aberrations that promote tumorigenesis. These primary genomic aberrations would be expected to occur at a high frequency in particular tumor types. We believe that altered loci detected in 22 of the 30 tumor samples (75%) may be significantly associated with tumorigenesis. In all, 24 spots were detected which showed a loss or reduction in intensity in 75% of the tumor DNA samples (see Table 2). The loss of these spots could have resulted from either of two primary causes: loss of hetrozygosity (LOH) (i.e. DNA loss) or methylation of the landmark *Not*I site. To distinguish between these two possibilities, we combined the information on spot intensity with that on chromosomal location. We assumed that chromosomal regions which displayed more than two contiguous loci/spot losses were likely to reflect the deletion of DNA as we had found previously,[20] whereas solitary loci/spot losses probably reflected methylation at the landmark sites. Confirmation of this assumption required the cloning of the spots and analysis of tumor-specific alterations by means of Southern blotting, using the spot clones as probes. By this means, we determined that loss or reduction in intensity of 14 solitary spots resulted from landmark methylation and, furthermore, that this methylation occurred in more than 75% of the tumor samples. These 14 spots are shown with their spot identification numbers in Figure 24(a). Part of the RLGS gel containing a representative spot, S238, is shown (indicated by the arrow) under magnification in Figure 24(b). The intensity of S238 is clearly reduced in tumor tissue. Characterizations of the 14 spots which displayed such reduced intensity are presented in Table 3. Locus number is designated as D#Rik- or D#Ncvs-. Each of the 14 spots were classified as solitary losses. Although four of the loci, D5Rik119, D5Ncvs4, D5Rik122 and D5Rik124, are located on chromosome 5, losses at these loci are all solitary. The localization of these four spots, however, is restricted to the centromeric half of the chromosome, indicating that a high frequency of methylation sites associated with tumorigenesis may be localized in this area.

Table 2 Numbers of RLGS loci exhibiting spot loss or reduction of spot intensity in tumor DNA[a]

Tumor DNA exhibiting loss or reduction in intensity of spots (%)	Number of loci
76–100	24
51–75	53
26–50	137
0–25	293

[a] Approximately 20 tumors were analyzed for each spot. [Reproduced from Akama et al.[30] by permission of the American Association for Cancer Research, Inc.]

5.2.4 *Isolation of Spot Clones and DNA Sequence Analyses*

In order to characterize further the nature of the genomic alterations associated with spot loss at the loci in question, and potentially to identify a gene at a given locus, we cloned 13 of the 14 spots using the restriction trapper-based RLGS spot-cloning method described in section 3.4.2.[30] DNA sequence analysis and a homology search against existing DNA databases revealed that two

Table 3 Solitary RLGS loci/spots with spot loss or reduction (methylation) in more than 75% of the mouse liver tumor samples

Locus	Spot	Methylation frequency (methylated/sample)	Sequence homology
D4Rik141	S6	29/30 (97%)	
D4Rik136	S238	24/27 (89%)	p16/CDKN2
D5Rik119	S189	29/30 (97%)	
D5Ncvs4	B18	27/30 (90%)	
D5Rik122	S178	23/30 (77%)	
D5Rik124	S130	23/29 (90%)	mac25
D7Rik89	S177	26/27 (96%)

D15Ncvs1	B330	27/30 (90%)	
D19Ncvs1	B391	29/30 (97%)	

of the cloned spots, S130 and S238, were identical with mouse mac25 and the mouse tumor suppressor gene p16/CDKN2, respectively.

5.2.5 *Southern Blot Analysis Using Spot Clone S238 as a Probe*

To examine the methylation status of p16/CDKN2 in tumor tissues, Southern blot analysis was performed using the cloned spot (S238) as a probe. Representative results are shown in Figure 25. The S238 probe used for hybridization is identical with the distal half of the first exon of p16/CDKN2. The S238 probe detects a *Pvu*II polymorphism between B6 and S in normal liver DNA (Figure 25, lanes 1 and 2). When these *Pvu*II–*Pvu*II fragments are digested with *Not*I, the S allele alone is cleaved into a 3.9-kb band (lanes 1 and 3), Thus, the *Not*I site from the spot clone S238 (*Not*I–*Pst*I fragment)

Figure 25 Southern blot analysis of normal liver DNA from B, S and mouse liver tumor DNAs from BSF1 animals. The DNAs were digested with *Pvu*II and *Not*I as indicated (+ or −). The size of each band is noted to the right and lane numbers are shown below. [Reproduced from Akama et al.[30] by permission of the American Association for Cancer Research, Inc.]

is present in the S allele but absent from the B6 allele. Lanes 5–12 are DNA from tumor samples digested with both *Not*I and *Pvu*II. In tumor XX-2 and K3-1 (lanes 5 and 6), the *Not*I–*Pvu*II 3.9-kb S allele is of reduced intensity whereas the 6.0-kb *Pvu*II–*Pvu*II S band is of increased intensity, indicating that the *Not*I site of the S allele has become methylated. Tumors L3-3, F3-1B and F3-5 show both methylated and unmethylated S bands of almost the same intensity (lanes 7, 9 and 10), suggesting that 50% of the S allele of the p16/CDKN2 gene has been methylated. Tumors B3-1 and N3-2C have no methylated 6.0-kb S band (lanes 8 and 12) but the intensity of the unmethylated 3.9-kb band is reduced, implying that the S allele of the p16/CDKN2 gene has been partially lost in this tumor sample. In tumor G3-2, both the methylated and unmethylated S bands are of reduced intensity and the B6 band is completely absent (lane 11), indicating that the S allele of the p16/CDKN2 gene is partially methylated and the B6 allele deleted.

5.2.6 *Methylation of p16/CDKN2 and Tumorigenesis*

Spot clone S238 was found to contain sequences identical to exon 1 of the p16/CDKN2 (INK4a, MTS1) gene. Homozygous and heterozygous deletion and also point mutations of this gene on 9p21 are commonly observed in human cancers.[47–49] Several reports also indicate that methylation of a 5′ CpG island which includes exon 1 is associated with transcriptional silencing of p16 in human tumors.[50–54] The product of the p16/CDKN2 gene, p16, binds to CDK4 and CDK6, preventing their interaction with cyclin D and subsequent cell cycle progression. The CDKN2 gene also encodes an unrelated protein, p19, which arises from an alternative reading frame. This protein (p19) is also capable of inducing arrested growth although the mechanism is not understood.[55]

Southern blot analysis of DNAs from liver tumors, using the S238 spot clone, indicated that the S *Not*I site within exon I was completely or almost completely methylated in 19 of 24 samples. Five samples showed partial methylation (Figure 25, lanes 8 and 12) or a combination of partial methylation and partial gene loss (lane 11). It is not known whether the tumors are heterogenous with respect to alterations at this locus. This region (exon 1) corresponds to the same region of the p16/CDKN2 gene which is hypermethylated in human tumors and results in transcriptional silencing.[54] Currently, it is not clear whether methylation silences p16 expression in the liver tumors analyzed in this study.

Since the liver tumors studied were induced as a result of SV40 T antigen expression, the Rb gene is presumably 'inactive'. P16 is considered to be upstream of pRb since it normally forms complexes with CDK4 and/or CDK6, inhibiting their interaction with cyclin D

and the subsequent phosphorylation of pRb necessary for cell cycle progression from G1 to S.[56] Hence it is difficult to perceive what the consequence of loss of p16 expression would be in an Rb-negative cell. Indeed, ectopic expression of p16 in Rb-negative cells does not result in G1 arrest.[56] Recent experiments indicate that p16 mRNA levels are normally elevated in Rb-negative cells or in SV40 T antigen-transformed cells, suggesting that Rb is normally a transcriptional repressor of p16.[57]

What, then, is the significance of p16 methylation and its presumed transcriptional silencing in the SV40 T antigen-induced liver tumors? Clearly, more work is necessary to elucidate the consequences of p16 methylation in this system. Recent studies indicate that D-type cyclins interact with a novel myb-like transcription factor, DMP1.[58] This suggests that cyclin D-dependent kinases may regulate gene expression through a mechanism independent of Rb. This pathway may function to link regulation of some genes with the cell cycle but may still be susceptible to regulation via p16–CDK4/CDK6 interaction. The methylation of p16 in the SV40 T antigen-induced liver tumors may perturb this pathway.

We conclude that RLGS-M can be used for a genome-wide search for tumor-related alterations in the DNA methylation status. RLGS-M can detect alterations in known tumor suppressor genes and provides a means for detecting and cloning novel genomic regions which have alterations in methylation status related to tumor progression.

Ribonucleic acids are negatively charged polymers assembled from four different types of monomers. Each monomer is made of an invariant phosphorylated sugar to which is attached one of the four standard nucleic acid bases; the pyrimidines uracil and cytosine, and the purines guanine and adenine. The first level of organization is thus the sequence of bases attached to the sugar–phosphate backbone. In salty water, the RNA molecules fold back on themselves via Watson–Crick base pairing between the bases (A with U, G with C or U) leading to double-stranded helices interrupted by single-stranded regions in internal loops or hairpin loops. The enumeration of the base-paired regions or helices constitutes a description of the second level of organization, the secondary structure. The methods available to deduce the secondary structure of an RNA molecule are mainly of three types: the phylogenetic approach, the theoretical prediction, and chemical/enzymatic methods. The secondary structure of an RNA molecule is experimentally accessible and its content measurable. Under appropriate conditions, structured RNA molecules undergo a transition to a three-dimensional (3D) fold in which the helices and the unpaired regions are precisely organized in space. This folding process usually depends on the presence of divalent ions, such as magnesium ions, and on the temperature. The tertiary structure is the level of organization relevant for biological function of structured RNA molecules.

1 INTRODUCTION

Ribonucleic acids are negatively charged polymers assembled from four different types of monomers. Each monomer is made of an invariant phosphorylated sugar to which is attached one of the four standard nucleic acid bases; the pyrimidines uracil and cytosine, and the purines guanine and adenine. The first level of organization is thus the sequence of bases attached to the sugar–phosphate backbone. In salty water, the RNA molecules fold back on themselves via Watson–Crick base pairing between the bases (A with U, G with C or U) leading to double-stranded helices interrupted by single-stranded regions in internal loops or hairpin loops. The enumeration of the base-paired regions or helices constitutes a description of the second level of organization, the secondary structure. The methods available to deduce the secondary structure of an RNA molecule are mainly of three types: the phylogenetic approach, the theoretical prediction, and chemical/enzymatic methods. The secondary structure of an RNA molecule is experimentally accessible and its content measurable. Under appropriate conditions, structured RNA molecules undergo a transition to a 3D fold in which the helices and the unpaired regions are precisely organized in space. This folding process usually depends on the presence of divalent ions like magnesium ions and on the temperature. The tertiary structure is the level of organization relevant for biological function of structured RNA molecules. Sections 2–4 discuss these structural properties of RNA.

The instrumental methods leading to the elucidation of the tertiary structure are then described. The first method relies on X-ray crystallography of single crystals of purified RNA molecules. The second most important structural method is nuclear magnetic resonance (NMR). Finally, the phylogenetic method coupled to computer modeling and experimental approaches is described. An overview of the RNA motifs underlying the assembly of RNA molecules in complex tertiary folds is given. These include loop–loop interactions, some of which constitute pseudoknots, tetraloops and their receptors, as well as structured internal loops such as the 5S loop E motif. The roles of non-Watson–Crick base pairing for tertiary structure is emphasized throughout.

2 CHEMICAL STRUCTURE OF RNA

Nucleic acid biopolymers comprise the DNA and RNA molecules. These two types of molecules possess very different functional roles. In brief, DNA molecules (deoxyribonucleic acids) contain the genetic code, whereas the more versatile RNA molecules (ribonucleic acids) are

Figure 1 Chemical structure of a ···AUGC··· RNA sequence drawn from the 5′ to the 3′ end. The RNA bases are frequently modified, especially in transfer RNAs (tRNAs), where thymine (5-methyl U or T) or pseudouridine (Ψ, in which there is a C–C glycosyl bond between the base C5 and the sugar C1′ atoms) are often found.

Figure 2 Possible interaction sites around the standard Watson–Crick base pairs G–C and A–U as well as the wobble G◦U pair and the sugar–phosphate backbone atoms. The edges facing the deep and shallow grooves of RNA helices are indicated. Hydrogen bond acceptor sites are marked by 'inward-pointing bold' arrows, hydrogen bond donor sites are marked by 'outward-pointing bold' arrows, weak hydrogen bond donor sites (C–H groups) are marked by thin arrows. The RNA 2′-hydroxyl group (see inset) displays simultaneously an hydrogen bond donor and acceptor potential.

involved in almost all crucial life processes and especially in the translation of the genetic code into proteins.

The four ribonucleosides that incorporate the purine bases, adenine (A) and guanine (G), and the pyrimidine bases, ucacil (U) and cytosine (C) constitute the basic building blocks of a RNA polymeric chain (Figure 1). These nucleosides comprise a ribose sugar ring and a purine (A, G) or a pyrimidine (C, U) base. They are connected together by a phosphodiester linkage. The nucleoside and its phosphodiester unit is called a nucleotide. The bases of an RNA polymeric chain associate with the complementary bases of the same chain or of another RNA chain by forming purine–pyrimidine A–U or G–C Watson–Crick base pairs (see Figure 2). The association of two self-complementary strands results in the formation of a right-handed double helical structure (Figure 3).

Although DNA and RNA molecules possess very distinct biological functions, chemically RNA differs from DNA only in two aspects: (a) the absence of a methyl group at position 5 of the uridine (U), and (b) the presence of a 2′-hydroxyl group of the RNA ribose sugar (Figure 1). These two small chemical modifications account for the profound functional and structural differences observed between DNA and RNA molecules. In contrast to DNA but similar to proteins, single-stranded polynucleotide RNA chains can fold in a variety of complex 3D structures.[1] This ability to form complex folds is exemplified by tRNA molecules which are constituted by a single chain of about 70 nucleotides (Figure 2).[2] The analogy with proteins includes also the fact that some RNA molecules, called ribozymes, are able to perform biologically crucial catalytic reactions.

In nucleic acids, there are six torsion angles in the sugar–phosphate backbone with an additional one between the base and the sugar (see Figure 5 in Berman's article **X-ray Structures of Nucleic Acids**). Sundaralingam reduced severely the variations in two torsion angles and constrained the other five to preferred domains of variations.[3] Thus, the torsion angles about the C–O bonds remain at about 180°, whereas the sugar rings adopt either the C3′-endo or the C2′-endo puckers and the base is either in an anti or a syn orientation with respect to the sugar. In proteins, the torsion angles on either side of the peptide bond constitute the main flexible links, whereas in nucleic acids the phosphodiester bonds themselves direct chain re-orientations.

The RNA molecules, in helical form (Figure 3), are not much affected by changes in their environment and adopt essentially the A-form in the helical parts of their structures under nearly all conditions.[4] However, many RNA molecules need specific divalent cations in order to fold properly into biologically active conformations.[5,6]

Figure 3 (a) Side and top views of the A-form adopted by RNA double helical structures. Notice the deep groove (corresponding to the major groove of B-DNA) and the shallow groove (corresponding to the minor groove of B-DNA). At the right, the 3D structure of a tRNA molecule resulting from the complex folding of a single polymer chain comprising 75 nucleotides is represented. (b) Schematic representation of the secondary and tertiary structures of yeast tRNA for aspartic acid. The dotted lines represent the tertiary pairs, which are except for one (G19–C56) of non-Watson–Crick nature. Notice the co-axial stacking between the acceptor and thymine helical stems as well as between the dihydrouridine (an uridine residue saturated at the C5=C6 bond) and the anticodon helical stems. At the interface between the dihydrouridine and anticodon stems there is usually a non-Watson–Crick pair. The thymine and dihydrouridine loops are connected via two important base pairs, a Watson–Crick G19–C56 and a bifurcated G18•Ψ55 base pairs. This spatial relationship between the secondary elements is further stabilized by triples between the single-stranded junctions (residues 8–9 and variable junction) and the deep groove of the dihydrouridine helix.

The absence of such ions may induce profound structural changes, such as loss of 3D interactions.[7]

Non-Watson–Crick base associations[8] are often found in RNA structures where they serve as specific recognition elements for proteins, nucleic acids, and ligands, or as ion-binding sites. Such noncanonical base pairs are linked by at least one interbase hydrogen bond and occasionally involve water-mediated base–base interactions. Wobble base pairs are typical of RNA molecules and can be inserted without great distortions into regular Watson–Crick helices.[9] The wobble base pairs display a characteristic shift of their Watson–Crick interaction sites. Two of these sites point, respectively, toward the shallow and deep grooves and are, thus, completely accessible to the solvent. Wobble base pairs comprise essentially the G◦U base pairs. For these base pairs, the guanine amino group protrudes into the shallow groove and the O4 atom of the uracil

Figure 4 Representation of the secondary and tertiary structure of an artificial group I intron based on that of *Tetrahymena thermophyla*. Some tertiary motifs are highlighted. Motifs I and II are loop–loop interactions leading to a helical structure maintained via standard Watson–Crick pairings. Motif III is constituted of a GUGA tetraloop interacting with the shallow groove of two base pairs embedded within a helix. Motif IV is made of a GAAA tetraloop interacting with its receptor, the 11nt-motif, a complex structure maintained by an AA-platform (two consecutive As in the same plane[26]) and an A•U Hoogsteen base pair. In motif V, part of an A-rich bulge interacts with C–G pairs in the shallow groove of a helix.

base point towards the deep groove. Furthermore, G◦U base pairs display a deep groove side that is lined with three hydrophilic acceptor atoms (N7, O6, O4) and no hydrophilic donor atoms, whereas the shallow groove side presents a cavity wide enough for trapping a water molecule. Both grooves present, therefore, very unique recognition patterns.[10]

3 DEFINITIONS OF SECONDARY AND TERTIARY STRUCTURES

Probably the most straightforward definition of secondary structure would include any nucleotide such that both itself and one at least of its immediate neighbors in the 5′ or 3′ direction are involved in classical (Watson–Crick and G◦U) base pairing with a stretch of nucleotides in antiparallel orientation (Figures 3 and 4). Ideally, one would like an RNA secondary structure to be a planar graph which can be represented as a tree, i.e. the lines connecting the paired bases do not intersect.[11] The secondary structure will define various elements. A hairpin loop is formed when an RNA strand folds back on itself. In an internal loop, at least one base is unpaired on each strand of the loop separating two paired regions. A mismatch is a special type of internal loop for which only one nucleotide is unpaired on each strand. A bulge has unpaired nucleotides on only one strand. The other strand has uninterrupted base pairing. A multibranched loop occurs when double-stranded regions separated by any number of unpaired nucleotides, come together.

In the next level of organization, the tertiary structure, the secondary structure elements are associated through numerous van der Waals contacts, specific hydrogen bonds via the formation of a small number of additional Watson-Crick pairs and/or unusual pairs involving hairpin loops or internal bulges. The parsing of energy levels between secondary and tertiary structures is reasonable in large RNAs, considering the relative energies and the clear identification of the secondary structure elements. In some cases, it is even possible to cut RNA molecules into modular domains which can re-associate only through tertiary contacts.

4 RNA TERTIARY MOTIFS

RNA tertiary structure comprises those interactions involving (a) two helices, (b) two unpaired regions, or (c) one unpaired region and a double-stranded helix. The interactions between two helices are basically of two types: either two helices with a contiguous strand stack

Figure 5 Two representations of a pseudoknot with a co-axial stacking of the two generated helices. Some consecutive bases (usually 6–8) of a hairpin loop are complementary, in the Watson–Crick sense, to bases either in the 5′- or 3′-strand leading to the hairpin. A second helix can, thus, be formed, once one hairpin is folded. In the classical type of pseudoknot represented (with segment L2 absent or with only one or two residues), the two helices can stack upon each other, leading to a stabilization of the tertiary motif. The single-stranded segments L1 and L3, which link stems 1 and 2, cross, respectively, the deep and shallow grooves of the contiguous helical stack to which they can make further base–base or base-sugar–phosphate backbone interactions.

on each other, or two distant helices position themselves so that their shallow grooves fit. An unpaired region belongs to either a single-stranded stretch (forming an internal loop or a bulge) or a hairpin loop closing a helix. Interactions between two unpaired regions lead to pseudoknots if a single loop is involved and to loop–loop motifs otherwise (Figure 5). Interactions between an unpaired region and a double-stranded helix can lead to various types of motifs. Pairing of a single-stranded stretch, either in the deep or the narrow groove of a double helix, yields a triple helix. One motif is known where the unpaired region constitutes a terminal loop, in which -GNRA- tetraloops bind the shallow groove of the helix (see Figure 6). Those motifs involving single-stranded stretches are especially rich in potential to form tertiary structure because they can lead to co-axiality between helices. Depending on their sequence, internal loops or bulges could constitute 3D motifs, but such motifs have not yet been characterized. The co-axial stacking of helices, together with specific helix–helix contacts or helix–loop interactions, lead to compact RNA assemblies, generally in the presence of divalent ions or polyamines (Figure 7).

5 INSTRUMENTAL METHODS

The experimental observations used for deriving a 3D structure, and thus the tertiary motifs, can be of quite different nature depending on the techniques employed.

Figure 6 The three main tertiary motifs mediated by the tetraloops of the GNRA family. In the first two (a) and (b), the third and fourth residues of the GYRA loop forms triples in the shallow grooves of helices so that G binds a U−A pair and A a C−G pair. In the third type of contact (c), a GAAA tetraloop binds a complex 11nt-motif with a central U•A in the Hoogsteen configuration. Each A of the loop binds principally a different base pair in the receptor.

Figure 7 Stereoview of the modeled architecture of the intron of *Tetrahymena thermophyla*.[27] Some of the tertiary motifs, shown in black, are numbered as in Figure 4.

These range from biophysical methods (X-ray diffraction data, NMR couplings or nuclear Overhauser effects, and other spectroscopic methods such as ultraviolet, Raman, or circular dichroism), to biochemical approaches (chemical probing or enzymatic attack), and biological data (sequences, phylogenies, and in vitro selection). High-resolution X-ray crystallographic analysis (diffraction data at 1.5–0.9 Å resolution) yields a wealth of unequalled 3D information. Nucleic acids are difficult to crystallize because they are highly charged macromolecules which, in case of RNA molecules, can undergo spontaneous cleavages. In addition, large, nucleic acids and especially RNAs, often exchange between various base pairings and foldings.

Recently, several new RNA crystal structures have appeared, extending our structural knowledge enormously since the days of the tRNAs.[1,12] Those developments were possible first following the introduction of methods for preparing RNA molecules on a large scale with either chemical synthesis or using the T7 DNA-dependent RNA polymerase and, second, following progress in crystallographic techniques especially cryocrystallography and the availability of synchroton sources (see the article **X-ray Structures of Nucleic Acids**). NMR has proved useful in this area (reviewed in the chapter by Eriksson **Nuclear Magnetic Resonance and Nucleic Acid Structures**). Chemical and enzymatic probing of nucleic acids in solution yields important information on the stability of the structures and on those bases protected from chemical or enzymatic attack. However, such experimental approaches do not reveal the nature of the interacting partners. Cross-linking experiments have the potential to give that information, but the cross-linking reactions take place in an assembly of molecules generally not all in the same state, and it is difficult to prove that the reactions occurred solely on functional molecules. Sequence data are extremely rich in potential 3D information, as they result from adaptative evolution over millions of years. Thus, if the function is identical and the sequences are sufficiently diverse, the noise level (or covariations resulting from contingencies) will be decreased by sequence comparisons.

5.1 Physical Methods

The physical methods used for determining RNA tertiary structure are described in other articles. The most accurate method relies on X-ray diffraction of single crystals (Figure 8), as reviewed in the article **X-ray Structures of Nucleic Acids**. The development of NMR spectroscopy has progressed and allowed the determination of several solution structures of free RNAs as well as of RNAs complexes with peptides, proteins or antibiotics. This approach is reviewed in the chapter by Eriksson **Nuclear Magnetic Resonance and Nucleic Acid Structures**. Most published structures are accessible and can be retrieved from the nucleic acid database (http://ndbserver.rutgers.edu/). The RNA tertiary structure is subtended by the secondary structure and this

Figure 8 The cumulative number of RNA crystal structures alone (light shading) and in complexes (in dark) accessible in the nucleic acid database (http://ndbserver.rutgers.edu/).

needs to be established before large-scale synthesis is envisaged for crystallogenesis or NMR experiments. The best way to derive secondary structures is by using sequence comparisons.

5.2 Phylogenetic Approach

When a set of homologous sequences (homologous sequences have common ancestry and function) is available, one can search, with the help of a rough alignment, for compensatory base changes that maintain base-paired helices and, therefore, derive the secondary structure. When only one sequence is available or when RNAs are not conserved among a sufficiently diverse set of organisms, theoretical models of predictions, have to be associated with experiments. The related knowledge is based on a set of constraints, the thermodynamic model, and the available experimental data on the molecule.

Comparative analysis of nucleic acid sequences has been widely used for the detection and evaluation of similarities and evolutionary relationships. With RNA molecules, sequence alignments and RNA 2D prediction are intimately related. Comparative analysis is based on the biological paradigm that macromolecules are the product of their historical evolution and that functionally homologous sequences will adopt similar structures. The sequences are first aligned and then searched for compensatory base pair changes. If, during evolution, a base has been modified in a strand of a potential helix (mutation), then this modification must have been compensated on the complementary strand in order to maintain the structure. The presence of several compensatory changes (two or more) in a potential helix allows one to assert the existence of the helix in the structure. Several secondary structure models have been generated by using comparative analysis: tRNA,[13] 16S rRNA,[14] or group I and group II self-splicing introns.[15] The method requires that the molecules compared are sufficiently different to provide numerous instances of sequence variations with which to test pairing possibilities but that the molecules do not differ so much that homologous residues cannot be aligned with confidence.[16]

In an alignement, the objective is to juxtapose related sequences so that homologous residues in each sequence occupy the same column in the alignment. Standard alignment programs dedicated to molecular biology can be used for that purpose. More recent programs, dedicated to the alignment of RNA sequences, allow the user to manipulate interactively the proposed alignment (such as DCSE,[17] ALIGNOS[18]). They offer functions

dedicated to secondary structures as well as an interactive environment for manipulating the alignment.

Other recent and interesting programs automatically reconsider the alignment by taking into account new sequences and the pre-existing knowledge of the secondary structure.[19] Indeed, with the growing number of sequences, specific RNA databases are created and new sequences have to be added quickly in structured databases of homologous RNA molecules. In such databases, it is very desirable that sequences are aligned in accordance with the preservation of secondary structural features. Because, in an alignment, optimal structural elements can be misaligned, the program RNAlign[19] makes it possible to align a group of aligned sequences with a new sequence, using positions of high sequence conservation as a guide and a common secondary structure of the group as a guide for determining the secondary structure of the new sequence. Thus, RNAlign does not suppose that the related sequences are correctly aligned but instead reconsiders the alignment.

5.3 Computer Modeling

Molecular modeling attempts to assemble the 3D structure of a macromolecule on the basis of a mixture of theoretical and experimental data. Hence, prediction methods range from mathematically oriented approaches, relying solely on computer algorithms, to pragmatic and operational approaches in which insight comes from both theory and experiment. Modeling can be viewed as a heuristic tool which should help in the rationalization of experimental observations but also should suggest new relationships between the various components of the modeled molecule. Modeling relies on an existing body of knowledge and, therefore, necessitates an integration of that accumulated knowledge in a form which can be exploited. Hence, the importance of organized and annotated data banks.

The power of visualizing spatial relations is such that models need not be always detailed. In the end, the validity and the accuracy of the model obtained will depend on the nature of the experimental observations collected. However, a mathematical proof guaranteeing the correctness of the derived model is only possible with crystallographic methods (the Fourier theorem). Otherwise, the best that can be achieved is a network of evidence converging on the spatial contacts and relations embodied by a model.

Because of the strong base-pairing constraints and the Watson–Crick rules of complementarity, modeling has had some success in the field of nucleic acids, starting from the Watson–Crick double helix. In the RNA field, modeling first proposed the structure of a GNRA tetraloop closed by a sheared G•A pair with stacking of the remaining purine bases.[20] Also, the relative arrangements of helices in group I introns were correctly assembled in a 3D model[21] long before X-ray crystallography led to supportive evidence.[22] Although such models lack correctness in atomic detail, they allow the deduction of new spatial relationships. Those, together with sequence analysis, permit the localizing of recurrent motifs serving as RNA–RNA anchors responsible for recognition and stabilization of folding in structured RNAs. In this way, the recognition motif between the GNRA tetraloops and the shallow grooves of helices was correctly identified[21] before being observed in intermolecular crystal packing contacts.[23] Similarly, the recognition motif between the GAAA tetraloop and its 11nt-receptor was identified by in vitro experiments using selection methods[24] before being observed by crystallography.[25,26]

6 CONCLUSIONS

RNA molecules are often restricted to their roles as intermediate between the genomic DNA and the active proteins. This view has changed following the discovery of catalytic RNA by S. Altman and T. Cech:[27,28] RNA is nowadays the only molecule with the two properties of being a depository of genomic information with catalytic potential. Chemical catalysis requires a precise positioning of atoms in space and, therefore, RNA must achieve complex tertiary folds in order to reach transition states. Because RNA molecules carry one negative charge per residue, the compact assembly of large RNAs presents a formidable physical problem. The architecture of large structured RNAs is dominated by helix formation and co-axial stacking of helical stems with loop–loop interactions and GNRA/motifs prevalent as domain anchors.[29] Although the recurrent tertiary motifs can be identified by sequence analysis coupled with chemical probing and 3D modeling, the precise and subtle atomic details require X-ray crystallography or NMR techniques in order to be unveiled.

The developments in chemical and molecular biology techniques have allowed the circumvention of some of the difficulties in the crystallization of RNA molecules and one can hope to see a continuous progression in the number of crystal structures of RNA molecules. Similarly, NMR spectroscopy has become a decisive tool for the unravelling of RNA motifs and complexes between RNA fragments and other ligands, such as antibiotics. Not every single RNA molecule is as highly structured as a self-splicing group I intron. However, it is common to find structured regions in functionally important domains of eukaryotic messenger RNAs, such as the 5′- or 3′-untranslated regions, in eubacterial promoters or

Shine–Dalgarno regions, and naturally in control regions of viral genomes. In addition, new structured RNAs are still being discovered, like the tmRNAs or the RNA part of the ribonucleic particle telomerase. Structured RNAs are often part of complexes with proteins, sometimes a single one as in RNaseP, or with 21 different proteins such as 16S rRNA in the 30S eubacterial ribosomal particle.

Sequencing by hybridization (SBH) determines the sequences of DNA or RNA targets using hybridization data obtained from sets of overlapping oligonucleotide probes of known sequence. SBH shares interesting parallels with computer-based keyword searches of text files. In SBH, chemically synthesized short oligonucleotides (usually 4–25 bases in length) are hybridized to the target under conditions that predominantly allow formation of fully complementary probe/target hybrids. An oligonucleotide hybridization search is effectively a highly parallel molecular computation process with fully random access to the polynucleotide chain ''input data''. The target sequence is assembled by aligning sequences of the subset of positively hybridizing oligonucleotides. Probe sequence overlap allows indirect assignment of which of four bases corresponds to each position in the analyzed DNA chain, without performing any actual positional measurements on the sample. The fundamental characteristics of the SBH process confer unique opportunities for miniaturization and parallel analyses (currently in the form of high-density arrays), leading to rapid, cost-effective DNA sequencing. A unique advantage of SBH is its ability to analyze in a single reaction complex DNA or RNA samples that may be thousands of bases long. Hybridization of smaller selected subsets of probes provides a very efficient way of partially sequencing and fingerprinting samples. A very important advantage of SBH is that in a single reaction each base is ''read'' by multiple overlapping probes. To achieve these advantages, hybridization reactions are miniaturized and coupled with automated data acquisition and efficient computational analyses that can process data sets containing both false-positive and false-negative probe scores. Successful assembly of long target sequences involves synthesis and hybridization of a large number of long probes, due to the higher probability that given short oligonucleotide sequences will be repeated within the target sequence. Overall, SBH is a rapid and cost-effective method of obtaining large amounts of accurate DNA sequence information.

1 INTRODUCTION

Living organisms are self-encoded systems that possess a precise set of instructions, recorded in the sequence

of their DNA or RNA, that uniquely specifies the organism's development and function. The nucleotide sequence of a DNA or RNA molecule is the specific order of nucleic acid bases in a polynucleotide chain that may be tens of millions of bases long. There are four bases commonly present in DNA: adenine, cytosine, guanine, and thymine (A, C, G, and T respectively). In its natural state, DNA is a double helical molecule, in which two complementary single-stranded DNA chains specifically intertwine with one another. Each purine DNA base in one chain recognizes and binds a specific pyrimidine partner in the other, A to T, and G to C. In this way, the sequence of each strand specifically and unambiguously defines the sequence of its complementary partner, which is of critical importance in the process of DNA replication and cell division.

The ability to efficiently read the sequences of genomic DNA or RNA molecules is essential to understanding and diagnosing genetic diseases, developing new medical treatments, engineering new traits in plants and animals, and unraveling developmental and evolutionary pathways of living organisms. Since the discovery of DNA's helical structure by Watson and Crick in the 1950s there have been intense efforts to develop biochemical, chemical, and physical methods to sequence individual genes or whole genomes. The efforts have culminated in the Human Genome Project, an international research project initiated in 1986, whose goal is to completely sequence the 3 billion nucleotides of the human genome.

The Human Genome Project, while of enormous importance, does not represent a complete answer to the many critical questions posed by human genetics. The maximum benefit of sequence information is obtained in comparative genome studies between various species and in correlation studies that relate individual sequence and phenotype differences. Such studies require sequencing the genomes of thousands of individuals and species. This situation has fueled a demand for dramatically more efficient ways of sequencing or fingerprinting DNA.

There are three principal ways to obtain partial or complete sequence information for a DNA fragment: (1) sequence-specific DNA degradation, synthesis, and/or separation; (2) sequence-specific DNA hybridization (strand pairing); and (3) nucleotide chain visualization. The first two approaches are currently used in many applications. Nucleotide chain visualization methods are still in the initial phases of development.

Within the first category of sequencing techniques, the automated Sanger gel electrophoresis method is currently most frequently used. This technique involves randomly terminating the synthesis of an unknown DNA at specific bases, followed by exact size (length) determination of the resulting DNA fragments.[1] The DNA fragments (all of which are synthesized from a single primer site) are then ordered by length to determine which bases are located at which sequence positions. Historically, RNA and DNA sequences were determined by chemical fragmentation techniques, such as the Maxam–Gilbert method,[2] or enzymatic fragmentation, such as various tRNA sequencing methods.[3] A number of variants of this basic scheme have been proposed, such as the cyclical removal or addition of single bases at the end of the sequenced chain.[4]

This article focuses on the second of the three principal sequencing approaches, the use of sequence-specific hybridization to determine primary DNA structure. The process takes advantage of one of the basic biochemical processes of life, the molecular specificity of pairing between two complementary DNA strands. Over the past decade, the use of oligonucleotide probes to sequence or fingerprint unknown DNAs by such hybridization methods has proved to be a highly potent and versatile way to obtain valuable genetic information.

Chemically synthesized oligonucleotides of known sequence allow a fast and informative hybridization search of a DNA sample, a process that is essentially similar to a keyword search of text by an Internet browser. Large sets of probes may be used to assemble an entire sequence, or smaller sets to obtain a ''fingerprint'' or ''sequence signature'' specific for a particular DNA. This article reviews the history, principles and experimental applications of DNA sequencing and fingerprinting by hybridization, and describes in detail several studies that demonstrate its tremendous potential as a method of analyzing individual genes or entire genomes.

2 ORIGINS OF SEQUENCING BY HYBRIDIZATION

Nucleic acid hybridization is the basis for all SBH methods. Hybridization is the sequence-specific process in which two polynucleotide chains recognize and bind one another at complementary sites. In 1960, Doty and colleagues at Harvard discovered that DNA molecules that have been denatured by heat or chemical treatment to form single-stranded chains can precisely pair or renature under the right reaction conditions.[5] Specificity of pairing is determined by base complementarity rules in which As from one chain bind to Ts in the other, and Gs bind to Cs.

Initial applications of hybridization in molecular biology (for example colony or Southern blot hybridizations) used nucleic acid probes longer than 50 bases that were derived from natural sources. The specificity and sensitivity of these reactions are such that sequences present at one part in a million can be readily detected. It is not

necessary for all bases in such a double-stranded hybrid to match perfectly; up to 1–2% mismatched bases may occur without affecting the strength of hybridization. The current widespread use of hybridization methods to identify samples containing previously isolated sequences is possible because natural sequences (i.e. genes) within a genome typically differ by far more than a few percentages in thousands of bases.

During the late 1970s and early 1980s powerful new research tools were developed to unravel the intricate sequences of DNA molecules. Caruthers and other researchers discovered ways to more efficiently synthesize specific DNA molecules on columns by stepwise addition of nucleotides.[6] These automated DNA synthesizers made possible the production of large numbers of specific oligonucleotides. In a parallel development, Bruce Wallace pioneered the use of such oligonucleotides as hybridization probes to confirm the existence of complementary sequences in target DNAs.[7]

As tools for detecting complementary sequences within a target DNA, oligonucleotide probes proved to be more sequence-specific than longer, natural probes. Wallace demonstrated that oligonucleotide probes 11–17 bases in length can be used to accurately detect single base mutations in defined DNA targets dot-blotted on a membrane.[7] He showed that such probes can be used to discriminate between perfect probe–target duplexes and those containing a single internal base mismatch.

Several years later, Saiki et al.[8] developed a ''reverse dot blot'' method of screening patient DNA samples for known mutations using oligonucleotide probe arrays. The method relies on an array of defined oligonucleotides designed to complement known mutations and corresponding wild-type sequences in a given gene, such as the human β-globin gene. Patient samples enriched in the particular gene sequence are then tested for hybridization against the array under conditions in which the formation of duplexes with an internal base mismatch is minimized. Positive hybridization of one probe (or two probes in the case of heterozygotes) confirms the existence of the mutation.

These early research developments provided basic research tools that were later used in developing methods for fingerprinting and sequencing DNA by oligonucleotide hybridization. They ensured essentially limitless supplies of oligonucleotides of any pre-specified sequence, and established the experimental conditions suitable for specific full-match hybridization using either target DNA or oligonucleotide probes bound to a support.

In 1986, Poustka and Lehrach[9] demonstrated that oligonucleotide hybridization can play a role in the field of DNA mapping. Their work showed that positive hybridization of an oligonucleotide to a cloned genomic fragment gives essentially the same mapping information as is provided by obtaining a single DNA band when cutting a cloned DNA with a restriction enzyme. In each case a specific short sequence is identified within the test DNA. With oligonucleotide hybridization, the identified sequence is identical in length and complementary in sequence to that of the oligonucleotide probe. The authors showed that hybridization ''fingerprints'' obtained with a set of short DNA probes can be used to identify overlapping cosmid clones sharing portions of their DNA.

In 1987, as a culmination of oligonucleotide applications in DNA analysis, Drmanac and Crkvenjakov[10] first proposed and later patented the method of SBH, in which the sequence of a DNA fragment is determined by hybridization with a sufficient number of short oligonucleotides of known sequence. The sequence is assembled from the subset of positively hybridizing probes detected by hybridizing a set of overlapping probes with the target DNA. The researchers presented an algorithm for reconstruction of DNA sequences as complex as the human genome that established the relationship between length and number of probes to length and number of clone fragments from the DNA being sequenced.[10,11] Hybridization of labeled probes to large arrays of clones was proposed as a method for sequencing complex genomes. Like the polymerase chain reaction (PCR) method, SBH radically expanded potential applications of the hybridization reaction. SBH is also thought to be more suitable for automation than classical sequencing methods.

Within a year of Drmanac and Crkvenjakov's patent application, other research groups presented variations of this new sequencing process. Bains and Smith[12] examined the process of sequence reconstruction from tetramers. In a 1988 patent application, Southern proposed a method for combinatorial in situ synthesis of complex oligonucleotide arrays on glass and hybridization of DNA to the array for mutation detection and complete sequencing.[13] Lysov et al.[14] also proposed SBH using an array of deposited oligonucleotides.

3 PRINCIPLES OF SEQUENCING BY HYBRIDIZATION

3.1 Hybridization Search Principle

SBH shares interesting parallels with conducting a computer search of a text file for a particular word or a phrase. In each case, a large string of characters is probed with a specific shorter string to detect matching sequences. In a computer text search, the search string or strings (key words) are used to browse a large Internet or local database to identify the subset of specific

Figure 1 Hybridization search of a DNA library. The schema depicts hybridization sites for four 5-mer oligonucleotide probes (shown in color) in four target DNA samples, as well as the resulting data pattern. Each DNA has a specific pattern reflecting the distinct subset of positive probes that hybridize with it. However, a hybridization search identifies only which probes hybridize to each sample, without indicating the order in which probe binding sites occur. For example, the result for the first sample is ''missing green probe,'' and for the fourth sample ''only green and yellow probes positive.'' The presence of two green probe binding sites in DNA sample 4 would not be detected unless hybridization intensity scores were evaluated instead of simple presence/absence data, as discussed in section 8. These ''presence/absence patterns'' may be used to identify the DNA (oligonucleotide fingerprinting) or, in combination with similar data from many overlapping probes, to determine its complete sequence.

documents containing perfect sequence matches, which is then retrieved for further review or analysis. In SBH, oligonucleotide probes ranging from 4 to 25 characters in length are used to browse libraries of DNA segments to identify DNA molecules containing exact complementary sequences. These molecules may then be further analyzed by mapping or clustering, or by partial or full sequencing.

Figure 1 shows the results of a hybridization search of four simple DNA samples with four different 5-mer probes (key words, strings) indicated by different colors. In this case, each sample binds a different combination of probes, leading to a characteristic color hybridization pattern. Each positive binding event in a given DNA sample provides a discrete piece of information about its sequence. Neither frequency nor location of the string within the DNA molecule is obtained from a hybridization search, as is also the case in most computer text searches. For example, a positive search result for the word ''tag'' in a set of document titles does not identify whether the word is positioned at the beginning, middle, or end of the selected titles, nor whether it occurs once, twice, or many times in any of these titles. Similarly, the entire DNA is sampled by random probe-binding trials, without determination of exactly where in the chain particular probes bind.

Thus, a DNA hybridization search is effectively a highly parallel molecular computation process with fully random access to the ''input data'', in this case a polynucleotide chain that may be thousands of bases long. These fundamental characteristics of the SBH process confer unique opportunities for miniaturization and parallel analyses, leading to speed and cost efficiencies not available with other sequencing methods.

In a computer search, the complexity of the English alphabet (26 letters) generally allows a meaningful search of a given text to be done with one or a few specific words. With a DNA search, the simple four-letter genetic alphabet requires use of either more or longer ''words'' (strings) to precisely identify a specific DNA. A simple word like ''cat'' might yield useful results in a computer search of the Internet, but the genetic triplet ''CAT'' occurs far too frequently (about once in every 64 triplets) to be of much use in DNA identification. The lengths of the DNA string (sequence) and the probe (interrogating string) are important parameters in devising a successful SBH experiment. By choosing appropriate probe and sample lengths, a researcher can obtain useful sequence data.

3.2 Probe Overlap Principle

The first potential probe binding site in a DNA chain starts at the first base and extends for the length of probe. The second probe binding site starts at the second base and overlaps the first probe binding site, less one base.

This means that if a complete (or sufficient) set of probes is tested, the end of each positive probe overlaps with the beginning of another positive probe, except in the case of the last positive probe in the target. This situation is illustrated in Figure 2(a), which shows the results of a hybridization search of a short 16-base DNA sequence with all 1024 possible pentamers. Positive hybridizing probes are indicated in boxes. Using the OP, the positive binding of just 12 of the 1024 possible 5-mer probes unambiguously determines the sequence of the target DNA (see Figure 2b). In each sequence assembly cycle, four potential overlap probes are checked. Starting with a positive probe AAATC, the next positive overlapping probe to the right may be AATCA, AATCC, AATCG or AATCT. Of these probes, only AATCG is found to be positive and is used for further assembly. The cycles are repeated in both directions until all positive probes are incorporated and the complete sequence is assembled. By extension, the same process applies to a longer DNA target if enough probes of appropriate length are used to identify uniquely overlapped strings within it.

The use of overlapping positive probes is a key aspect of SBH methods. The OP allows the identification of sequences within a target DNA that are longer than any of the probes used in the assembly process. Probe overlap allows indirect assignment of one out of four bases for each position in the analyzed DNA chain without performing any actual positional measurements on the sample. The base/position information is in fact derived from the known sequences of the oligonucleotide probes obtained by accurate chemical synthesis.

Because the sequences of DNA molecules are nonrandom and irregular, statistical artifacts arise that must be addressed in SBH experiments. Even when the lengths of DNA targets and probes are selected to achieve a statistical expectation that each probe sequence occurs no more than once in the target, so-called ''branching ambiguities'' can occur.[10,11] Take the case of three probes that positively hybridize to a target DNA: TAGA, AGAC and AGAT. Both the second and the third probes overlap with the first probe, sharing the bases AGA and giving extended sequences TAGAC and TAGAT respectively. Owing to the occurrence of the sequence AGA in both the second and third probes (e.g. because of double AGA occurrence in the target), there is not enough information available to decide which of the two probes is actually the one that overlaps with the first probe in the sample. Sequence assembly can thus proceed along either of the two branches, only one of which is correct.

By using all probes of a given length (as in Figure 2a), a researcher can unambiguously determine a target sequence, provided the target DNA is short enough that most overlap sequences occur no more than once. The only other exception to this rule is tandem repeat regions (e.g. AAAAAAAAAA, ACACACACAC) that are longer than the probe length. In such cases, the exact length of these repeats may be determined by use of a special subset of longer probes. Longer targets may require longer probes for unambiguous sequence determination. Table 1 shows the exponential increase in the number of possible probes as a function of probe length. A variety of ways have been proposed to increase the read length with a given set of probes, or to reduce the number of experimental probe/target scores needed to sequence a target DNA. These include the use of pools of probes, competitive hybridization and overlapped clones,[10,11] gapped[12] and binary[15] probes, continuous stacking hybridization,[16] and the simultaneous sequencing of similar genomes.[17]

The information needed to solve branching ambiguities is directly provided by using a reference gene sequence when assembling gene sequences from individual patient samples. When a reference sequence is known, the maximal read length in bases may be extended to approximately one-tenth the number of probes used (Table 1). To sequence human and other complex genomes (over 3 billion base pairs) as a single sample, about 70 billion 18-mer

Table 1 Relationship of probe length, number of possible probes, and sequence read length

Number of nucleotides in probe (n)	Number of possible probes[a] (4^n)	Basic read length[b] (bases)	Enhanced read length[c] (bases)
3	64	6	6
4	256	12	25
5	1024	25	100
6	4096	50	500
7	16 384	100	1500
8	65 536	200	6500
9	262 144	400	25 000

12	16 777 216	3200	1 500 000
14	268 435 456	12 800	25 000 000
16	4 294 967 296	51 200	450 000 000
18	68 719 476 736	204 800	7 000 000 000
20	1 099 511 627 780	819 200	100 000 000 000

[a] The number of possible oligomer probes increases exponentially as a function of probe length. Short probe sequences (3- to 4-mers) occur so frequently in a target DNA that their use in SBH experiments is impractical except for the shortest DNAs. Probes longer than 12 bases are usually used in well-defined sets corresponding to a known target due to the huge numbers of possible probes.

[b] The ''basic read length'' is that target length which, for a given probe length, has a 95% chance of unique assembly. The length is very approximate for probes shorter than six bases.

[c] The ''enhanced read length'' is that target length which provides on average about 10% positive and 90% negative probes and less than one end-mismatched binding site per probe.

Figure 2 Probe overlap principle (OP). (a) Rare but overlapped positive probes. Hypothetical SBH experiment showing a 16-base DNA sample hybridized with the complete set of 1024 5-mer oligonucleotides. Probes are written in the 5′–3′ direction, and are sorted alphabetically in vertical columns. Positive-binding probes are indicated in boxes. The sequences of positive probes complement the strand present in the experiment and are identical to its complementary strand. The first binding site at the beginning of the target is for probe TAAAT and the second for probe AAATC. These two probes overlap over the four-base sequence AAAT. Every positive probe site (except at the target ends) has two probes overlapping four bases, one in each direction. Only about 1.2% of all probes are positive, with negative probes dominating. In most SBH experiments fewer than 10% of the probes used are positive. (b) (See overleaf) Sequence assembly. Positive overlapping probes from the above SBH experiment are used to assemble the target DNA sequence. In this case, assembly starts with the first positive probe in the alphabetical order (probe AAATC). The assembly process involves defining the end sequence of the initial, or last incorporated probe (AATC in this case), and then checking which of four probes that start with that defined sequence (AATCA, AATCC, AATCG, or AATCT) is positive (AATCG in this case). The new search sequence ATCG is thus defined for the next cycle. Ten probes are found to align to the right and only one to the left. Every base (excluding a few bases toward the target ends) is read with five overlapping probes (seen as vertical columns of five letters). In general, the number of overlapped probes reading each base equals the number of bases in the probe.

Figure 2 (*Continued*)

probes would be needed. With appropriate detection sensitivity and process miniaturization this astonishing task may someday be accomplished in a single hybridization experiment. SBH may be the only sequencing method that has the capacity for whole genome analysis in a single reaction.

4 VARIATIONS OF THE SEQUENCING BY HYBRIDIZATION METHOD

Three basic variations of the SBH method have been developed, as illustrated in Figure 3. These are discussed below.

4.1 Format 1 Sequencing by Hybridization

Format 1 SBH[10,11] involves using an array of target DNAs exposed to a single labeled oligomer probe or small probe pool in a hybridization step. After washing to remove unbound probe, arrays are scored for signal intensity. As shown in Figure 3, probes that do not match (or only partially match) the target are removed by washing. A subsequent more stringent wash is then used to remove hybridized probe, leaving the array ready for the next hybridization cycle. Probes are applied consecutively to a single array (or replica arrays) of

Figure 3 Schema of the three major SBH formats. In each case two probe or DNA spots are shown before and after hybridization and after a stringent wash to remove mismatch probes. In Format 1, target DNA samples (shown as orange and yellow bars) are bound to a solid support and tested for hybridization with labeled (red) probes in solution. A mismatched probe (left spot) binds poorly and is removed in the wash. In Format 2, blue and green probes (attached directly or through an adapter) are bound to a solid support and tested with a labeled DNA sample (yellow) in solution. In Format 3, bound and labeled probes hybridizing at adjacent positions on a target DNA are ligated to form a stable, covalently linked probe structure that identifies a longer complementary sequence in the target. Mismatched probes or those that bind to nonadjacent sites do not ligate and are removed in the wash step.

sample DNAs in a series of hybridization reactions. After all probes from a set have been tested, the subset of probes positively hybridizing to each sample is used to compile its fingerprint or exact sequence. An advantage of Format 1 SBH is that optimal hybridization conditions can be applied because only one probe (or small probe pool) is used at a time, minimizing the variety of different probe–DNA hybrids. This format is effective in analyzing large sets of samples.

4.2 Format 2 Sequencing by Hybridization

In Format 2 SBH,[13,14] a set of probes is attached in an array pattern on a support. A labeled, fragmented DNA sample is then hybridized to the probe arrays. The sample DNA sequence is assembled from the set of positive probe–DNA hybrids that remain after unhybridized DNAs are removed by washing. A disadvantage of Format 2 SBH is that a large variety of probe–DNA hybrids with different thermodynamic stabilities is formed and scored in a single hybridization reaction. A variant of Format 2 SBH (see Figure 3) was proposed by Broude et al.[18] in 1994. In this variation, probes are not end-attached single-stranded molecules, but consist of duplex anchored DNAs with single-stranded tails. The hybridization of target DNAs is facilitated by a stacking interaction with the abutting strand of duplex DNA, and each positive hybridization is converted into a stable covalent bond by the enzyme ligase. This method requires very precise sample fragmentation. To be able to score all probes a fraction of the target molecules has to be cut at each base.

4.3 Format 3 Sequencing by Hybridization

In the early 1990s, Drmanac[19] proposed Format 3 SBH, an advanced combinatorial method capable of scoring extremely large numbers of probes. Two sets of probes are used in Format 3 SBH (see Figure 3). One set of unlabeled probes is covalently bound to the support. An unlabeled target DNA sample is then hybridized to the bound probes, in the presence of a second set of labeled probes and DNA ligase or another coupling agent. When the labeled and unlabeled probes hybridize to the target DNA at precisely adjacent positions (see Figure 3) they are joined to form a labeled two-probe construct covalently bound to the support. Hot washing removes any labeled probes that are not ligated, as well as the target DNA, leaving only the two-probe constructs to be scored as positive signals. This format allows combinatorial scoring of a large number of probes by preparing two small sets of short probes. For example, over 1 million 10-mers can be scored using just two sets of 1024 5-mers. The combinatorial aspect arises from the arrangement of subarrays of bound probes in a larger superarray, each subarray being exposed to one labeled probe or probe pool in a single hybridization reaction. The superarray may contain as many subarrays and hybridization chambers as there are labeled probes or labeled probe pools to allow their simultaneous scoring. The use of two short probes, a unique feature of this SBH format, provides better discrimination than would be achieved with other formats using probes twice as long. In addition, there is no need to cut the target DNA at each base pair, as is required in the Format 2 ligation approach.[18]

In all SBH formats, a DNA polymerase elongation reaction may be used in addition to probe hybridization[18–20] in the scoring process. In this case, unlabeled probes act as primers, and are extended by DNA polymerase by at least one labeled base after hybridization. By using four different labels, one for each of the four dideoxy nucleotides, probes may be specifically extended by one base before final scoring.

5 APPLICATIONS

Oligonucleotide hybridization is a flexible method of screening and sequencing DNA samples. By selecting appropriate combinations of probes and samples, oligonucleotide hybridization can be used for a wide variety of applications ranging from DNA fingerprinting to complete sequencing. There are five general types of applications for oligonucleotide hybridization (Table 2):

Table 2 SBH applications in genomics research

Application	Principle[a]	No. of probes (in a typical test)[a]
Clone contig mapping	SP	>50
cDNA clone clustering/ partial sequencing	SP (OP)	>100
Known polymorphisms/ mutation detection	SP (OP)	>100
Novel polymorphisms/ mutation discovery	SP, OP	>250
De novo sequencing	SP, OP	>4000

[a] The numbers of probes used varies dramatically depending on the application, from ten to a few hundred in simple DNA fingerprinting to tens of thousands in some de novo sequencing applications. Each application takes advantage of one or both of the basic principles that underlie SBH methods: the search principle (SP), in which the presence of complementary oligonucleotide sequences within a target DNA is determined, and the OP, in which overlapping positive probes are used to assemble a target sequence.

- clone contig mapping over a wide range of clone lengths;
- clustering, motif searching, or partial sequencing of cDNAs;
- scoring known polymorphisms and mutations, including single nucleotide polymorphisms (SNPs);
- individual DNA sequencing for discovering novel polymorphisms or mutations;
- de novo sequencing.

The number of probes used and the informational principles behind each application vary widely depending on the experimental goals. Only about 100 probes are needed to obtain clone contigs and cDNA clusters, procedures that involve only the hybridization SP. For partial sequencing and detection of known mutations the number of probes used may range from a few oligonucleotides in some simple applications to thousands in others. When overlapped probes are used to sequence DNA, the probe OP is employed, in addition to obligatory use of the hybridization SP. For discovery of novel mutations or polymorphisms, both search and OPs are used, and the number of probes used may range from complete sets of 4-mers up to complete sets of 20-mers. Another possibility is to use incomplete sets of longer probes, ranging from 7 to 30 bases. Nucleic acid samples can vary from a few hundred bases in length, such as short PCR products, to lengthy cellular mRNAs or genomic DNAs. Each of these five basic oligonucleotide hybridization applications is discussed in detail below.

5.1 Clone Contig Mapping Over a Wide Range of Clone Lengths

Oligonucleotide hybridization can be used to identify overlapping clones that contain identical sequence strings.[9] Since overlapping cosmids share common sequence regions they should show significantly larger numbers of shared positive probes than would be statistically expected from a randomly selected set of oligonucleotides. The authors demonstrated that a set of 100 randomly chosen 12- to 16-mer oligonucleotides is generally sufficient to identify and order cosmid clones if the neighboring overlapped clone pairs share more than 30% of their sequences. The first real application of this idea was the construction of cosmid maps of a yeast genome in 1993.[21] This method, which can be used for long-range mapping of large cosmid or BAC (bacterial artificial chromosome) clones, relies on using a set of 100–200 12- to 16-mer oligonucleotides and additional longer repetitive DNA probes.

Long-range maps of such cosmids and BACs, obtained either by the above-described application of oligonucleotide hybridization or by classical restriction mapping techniques, are necessary for gene cloning and genomic sequencing projects. The BAC or cosmid clones chosen from the maps are generally subcloned into 1- to 5-kb fragments suitable for gel sequencing or SBH. These subclones can be either sequenced randomly in a shotgun approach by gel, or fingerprinted using Format 1 DNA arrays to map or group highly redundant clones. This fingerprinting procedure typically reduces the number of redundantly sequenced clones by 3- to 6-fold,[22,23] resulting in substantial cost and time savings. The map can be constructed by obtaining sequence signatures with a few hundred 7-mer probes from the sufficient number of 0.5- to 2-kb subclones (20 equivalents of the map length).

5.2 Clustering, Motif Searching, and Partial Sequencing of cDNAs

DNA sequence signatures provide a powerful tool for identifying new genes. Drmanac originally proposed obtaining sequence signatures in 1990, using Format 1 as an efficient, high throughput method for characterizing cDNA libraries.[24] Clones arising from the same genes are clustered together based on their similar hybridization signatures. A single representative of each cluster may then be sequenced, dramatically reducing the number of clones that must be sequenced compared to the randomly selected, repetitive DNA sets obtained by the expressed sequence tags (EST) method. This hybridization method has been used extensively[25–27] and is discussed in detail in section 9. At Hyseq, Inc., by processing over 1 million clones per month in various projects, hybridization signatures for over 15 million cDNA clones have been generated and tens of thousands of novel, rarely expressed genes discovered.

Using a large probe set, samples whose sequences are already present in databases can be identified without resorting to complete sequencing.[26,28] A more narrowly directed set of probes can be used to detect coding sequences for any and all variants of a protein motif present in cellular mRNAs. The use of incomplete sets of probes to interrogate only certain segments or types of sequences in the target is called partial SBH.[24]

The gene clustering data obtained from Format 1 SBH experiments are also used to accurately measure gene expression in a given cell or tissue. The size of a cluster for a specific gene is a direct measure of that gene's activity within the test tissue or cell line. This method provides new breadth and precision in monitoring gene expression in any tissue or cell line from which a cDNA library has been prepared. No previous knowledge of which genes are expressed or their sequences is necessary for the analysis. The method allows statistically verifiable results to be obtained by directly counting rarely expressed genes for the first time.[25–27] Comparative analysis of cDNA

libraries from diseased and normal tissues provides a comprehensive list of which genes are up- and down-regulated in the disease process.

Lockhart et al.[29] applied oligonucleotide arrays to measure the expression of previously discovered genes that had been sequenced. In this application, adjacent cells in an array contain a variety of 15- to 25-mer oligonucleotides. For example, a 4000-gene array might contain 80 000 different oligonucleotide spots, with roughly 20 spots corresponding to each mRNA. Manufacture, hybridization, and scoring of these miniaturized arrays are analogous to those used in the sequencing applications described below. When cellular mRNA mixtures are hybridized to the probe array, the signal strengths obtained are in theory proportional to the amounts of specific mRNAs in the mixture, and hence provide a measure of gene activity. Researchers at Affymetrix, Inc. (Santa Clara, CA) have recently reported oligonucleotide arrays representing 30 000 mouse and 40 000 human genes selected from public databases.

5.3 Detection of Known Polymorphisms and Mutations, Including Single Nucleotide Polymorphisms

Since 1979,[7] various hybridization methods have been developed to detect and identify known gene mutations and polymorphisms, including SNPs. An electronic variant of oligonucleotide probe arrays has been developed to detect the presence of known mutations or specific microorganisms in environmental samples.[30] In this method, DNA from lysed bacteria is concentrated and fragmented, then hybridized to a microarray of sequence-specific oligonucleotide probes.

The large arrays currently used in both Format 1 and Format 2 applications allow simultaneous scoring of many independent sequence sites in complex nucleic acid samples. The hybridization search process, with its random parallel access to all potential target sequences, determines which sequence variant or allele is present at each interrogated site. For instance, single arrays can be designed to interrogate 1000 potential mutation sites within 100 genes using complex cDNA mixtures obtained from a single patient. For the first time, such methods allow development of DNA diagnostic population screens.

One approach being vigorously pursued in human genetic mapping involves scoring thousands of SNPs from individual members of affected families or selected population samples. Format 1 arrays of 55 000 pools of 10 to 100 DNA amplicons prepared from individual genomic DNA samples allow extremely efficient population genotyping of known polymorphisms or mutations. Consecutive hybridization of a few probes per allele permits the scoring of millions of genotypes per day. In a complementary approach, Format 2 SBH arrays have been developed that allow simultaneous scoring of 500 SNPs for each individual patient using a set of overlapped probes for each allele.[31]

A comprehensive survey of defined functional SNPs might comprise about 1 million genomic sites that exhibit greater than 1% polymorphism frequency and are known or expected to influence phenotype. Such a survey could be used to obtain an almost complete diagnosis of the health of what is arguably the body's most important organ, the human genome. This type of patient genome description or "Genogram"[32] should prove to be of enormous medical importance. With proper miniaturization, for example using arrays of micron- or submicron-size beads,[32] Format 3 SBH is probably the best-suited technique for this application, which would require high-fidelity testing of several million probes more than 10 bases in length.

5.4 Discovery of Novel Polymorphisms or Mutations by Individual DNA Sequencing

This application usually requires large or complete sets of oligomer probes. A common procedure is to use all probes corresponding to a given reference sequence. In 1991, Strezoska et al.[33] demonstrated the potential of using Format 1 SBH to confirm the absence of base changes in an individual DNA sample. Using 100 octamers corresponding to a known 100-base sequence, the researchers were able to accurately assemble the test sequence based on the hybridization results obtained. The use of several overlapping probes to test each base assured high accuracy. In a more advanced application, Drmanac et al.[34] used a complete 7-mer probe set to accurately sequence over 10 000 bases of p53 exon DNA from a number of samples. The accuracy, turnaround time, and throughput of this Format 1 application make it suitable for the large sample volumes used to detect rare polymorphisms. The use of complete sets of probes allows the sequencing of any gene, and can determine virtually all types of mutations and polymorphisms. This work is discussed in detail in section 9.

Southern et al.[35] demonstrated the use of Format 2 SBH to sequence 24-base model targets using a 256-member array consisting of all possible 8-mer probes made up entirely of purines. Subsequently, researchers at Affymetrix, Inc., developed Format 2 SBH methods designed primarily for sequencing certain variants of individual DNA samples when a prototype sequence is known.[36] Using lithography, they produced miniaturized arrays consisting of sets of 18- to 25-mer oligonucleotide probes that are designed to detect unchanged sequences and those with single base substitutions. Probes are selected so that each base in the target sequence is covered

by four oligonucleotide probes that are identical except for one centrally placed base that varies in each of the four oligonucleotides. Large probe arrays may be able to analyze DNA segments several kilobases in length.[36] Since this method uses a very select, partial set of long probes, some mutations may be detected but cannot be precisely sequenced, particularly in the case of insertion mutants. Sequence-specific arrays have been constructed and used to sequence the HIV clade B protease, BRCA1, and ATM genes.[37–39]

Broude et al.[18] proposed the development of universal microarrays containing duplex DNA anchors with all possible single-stranded *n*-mer tails. This variant of the Format 2 SBH procedure involves ligation of the target DNA to matching probes. Gunderson et al.[40] used this method to sequence approximately 1 kb fragments of the HIV pol and cytochrome *b* genes in test DNA samples. The researchers used complete arrays of 8-mer and 9-mer probes.

Hyseq, Inc., has developed the HyChip™ system for accurate complete sequencing of any candidate gene (including heterozygotic sites) in individual genomic DNA samples and discovery of all types of polymorphisms and mutations. The HyChip™ system scores all possible 10-mers (1 048 576 combinations) using a Format 3 SBH ligation procedure involving two sets of 5-mer probes.[19] A sequence read length of 2000 bases has been demonstrated (S. Drmanac et al., paper in preparation).

The examples above demonstrate that SBH can provide accurate and efficient polymorphism discovery, information that is of critical scientific and medical importance. There is a growing need to sequence most of the genomic DNA of perhaps 1000 individuals to discover significant human polymorphisms (those with 1% frequency or greater) for correlation studies, and to develop Genogram tests for diagnosis.

5.5 De Novo DNA Sequencing

De novo sequencing of complex genomes is the most challenging SBH application.[11] Successful sequencing of different DNA fragments has been reported by some researchers. Drmanac et al.[41] demonstrated the accuracy of the SBH Format 1 technique by sequencing unknown short primate DNA sequences using a set of octamer oligonucleotides in a blind test. The probe set contained both exact match and mismatched probes and was tested against three 116 base pair homologous regions obtained from different primate T-cell receptor loci. Exact sequences were determined without a single error. False-positive probe hybridization was found to occur infrequently and was easily corrected due to the high data redundancy inherent in the SBH method.

In 1996, Hyseq, Inc., researchers sequenced nearly a million bases of cDNA clones using a combination of data obtained from single-pass gel sequencing and from a complete set of 7-mer probes scored by Format 1 SBH (unpublished data). Blind tests of Format 3 SBH demonstrate the reliability of using hybridization and ligation of adjacent probes to sequence unknown DNA samples (S. Drmanac et al., paper in preparation). By scoring all possible 10-mers (obtained by ligating two 5-mers) using HyChip™ 5-mer arrays, sequences as long as 800 bases may be assembled directly from the hybridization data (see Table 1). In the future, scoring longer probes (e.g. 14-mers) using pools of distinctly labeled 6- to 7-mer probes and miniaturized arrays of 7- to 8-mers may provide de novo read lengths of 10 kb or more, a task that is difficult if not impossible to achieve with nonhybridization sequencing methods.

6 BIOCHEMISTRY

6.1 Sample Preparation

Most current SBH applications, with the exception of Format 2 expression studies, use nucleic acid samples ranging in length from 200 to 2000 bases. Initial DNA samples are typically obtained by cloning or PCR. Some samples, such as multiplex PCR preparations, are mixtures of fragments, with a total length of up to several kilobases of DNA. PCR is the dominant preparation method, due to its ease of use, reproducibility, and high yield. Plasmid and phage preparations have also been used.[41,42] High-throughput PCR procedures have been developed to create the large DNA arrays used in Format 1 SBH applications.

Figure 4 shows the outcome of PCR preparations of 22 genomic DNA samples obtained from individual patients. A 10^8-fold amplification of as few as 100 copies of a ~1 kb ApoB gene segment was achieved, with only a two-fold yield variation between samples. Negative controls with no patient DNA have undetectable signals. Cross-contamination of up to 5% in the final arrayed samples can be tolerated due to the small contribution (below the level of mismatch signals) of such contaminants to the signal.

Throughputs of up to 50 000 PCR reactions per day are routinely achieved for current Format 1 SBH gene discovery projects.[43] Initial samples for PCR preparations may consist of cloned DNA in bacterial plasmids or purified genomic DNA. The small amounts of proteins and other contaminants present do not hinder the hybridization reaction, allowing simplified, automated sample preparation.

In order to prevent secondary structure formation within the target DNA prior to exposure to probes in Format 1 SBH, denatured target strands are anchored

Figure 4 Sample preparation for an ApoB gene segment. PCR of a 967 base pair ApoB amplicon is performed on 22 patient DNA samples and run on an agarose gel with size markers (M1, M2). The 40 ng DNA bands are obtained by 10^8-fold amplification from about 100 initial chromosomes. There is no visible contamination in negative control reactions having no patient DNA.

to the substrate by a pseudo-covalent bond every 30–50 bases, thus preventing renaturation. In Formats 2 and 3 SBH, the target DNA is fragmented into small pieces about the size of the probes and then denatured, to assure that internal secondary structures within the target are less stable than probe–target duplexes. Under the excess probe conditions used, such target–target duplexes are simply out-competed kinetically. Owing to its amenability to fragmentation and labeling, the final target in most Format 2 SBH applications is RNA synthesized from clone inserts.[35–39]

6.2 Probe Preparation

Oligonucleotide probes may be synthesized quickly and accurately on modern DNA synthesis machines, with thousands of specific, high-quality probes produced in a few days. In some applications, additional purification of oligonucleotides by gel or column chromatography is necessary. No such purification is necessary for Format 1 procedures. In commercial batches of several thousand unique probes, less than 5% typically prove to be unsuitable for hybridization due to impurity or improper synthesis.[34] In Format 2 SBH (especially when ligase is used) and Format 3 SBH, probe purification is appropriate to avoid shorter products. In the case of in situ synthesis of probe arrays no purification procedure is possible, creating potential quality control (QC) and reproducibility problems between arrays.[35–40]

An additional concern with in situ synthesized miniaturized arrays is the density of probe molecules per spot. The density of usable probe strands per unit of surface area is a critical factor in determining signal strength. Too few or too many probes (which prevents target access) results in low or undetectable signals.

For a variety of reasons,[11,12] pools of probes are sometimes synthesized by incorporating more than one type of base in a single base-addition cycle. With such degenerate probes the goal is that equimolar incorporation of all bases occurs. To assure this condition, it is necessary to premix bases in proper ratios instead of depending on correct uptake by instrument pumps.

Most current SBH applications use natural bases. Modified bases may be used to equalize hybridization strength for G + C-rich and A + T-rich probes, and to modulate the overall stability and specificity of base pairing. Many initial studies are underway to test how these factors are affected by different chemical modifications of natural bases. The base modifications must be compatible with DNA ligase and polymerase or other enzymes if these enzymes are part of the probe-scoring process.

6.3 Array Chemistry

In preparing DNA arrays, attachment of strands to the solid substrate is maximized to reduce the quantity of soluble DNA or label needed to produce a strong signal. In addition, nonspecific binding of labeled stand to either the substrate or bound probes is minimized to reduce the background signal. This is achieved by choosing inert substrates or adding appropriate components of hybridization buffers that minimize or compete for nonspecific binding sites. In Format 1 SBH, the nylon membranes used for making arrays are typically a mesh of fibers, allowing three-dimensional binding via pseudo-covalent bonds. Subsequent ultraviolet cross-linking of T bases produces covalent interstrand bonding, leading to retention of a higher proportion of input strands. Approximately 60–90% of the initially bound DNA is retained, even after repeated cycles of hybridization and washing. In Format 2 SBH the substrate is usually flat, nonporous glass. The density of bound probes is a direct function of the number of activated sites per unit surface suitable for attachment of either pre-made oligonucleotides or initial monomers used in subsequent in situ synthesis. The probe density achieved is a function of surface activation and coupling chemistry. Other potential substrates include polyacrylamide gel-coated glass[15] or micro beads.[32]

6.4 Labeling

The soluble DNA strand in an SBH array experiment, whether probe or target DNA, is usually labeled to allow scoring of hybridization events. Any part of the strand

may be labeled, but typically the terminal base of a probe or target DNA fragment is chosen. The labeling procedure may be enzymatic or chemical. For instance, in Format 1 SBH applications, polynucleotide kinase adds a ^{33}P-labeled phosphate group on the 5′ end of oligonucleotides, while in Format 2 SBH applications, RNA polymerase is used to incorporate fluorescent-labeled RNA bases to create a multiple chromophore attached to the target DNA. Labeled groups can also be added during chemical synthesis of oligonucleotides. The most common labels are radioactive or fluorescent tags that are readily quantified by advanced detection devices such as Phosphoimagers (Molecular Dynamics, Sunnyvale, CA) or fluorescence scanners (GSI Lumonics, Inc., Watertown, MA).

Radioactive tagging is the traditional labeling method used in nucleic acid chemistry and is still widely used in Format 1 SBH applications. ^{33}P has several advantages as a radioactive label for nucleic acids. One is an optimal α particle energy, which provides the rapid, sensitive detection characteristics of higher-energy nuclides, but with the high resolution and added workplace safety of a particle that exhibits minimal air penetration (less than 1 cm). The other advantage is a short half-life, requiring only a 6-month decontamination period for any radiolabeled wastes. ^{33}P-labeled array spots need to be at least 200–300 μm apart to be successfully resolved, and the lower limit of detection is about 10 labeled duplexes per square micrometer.

Fluorescence labeling can be direct, in which case an organic chromophore is covalently attached to the DNA, or indirect, such as when a tag attached to DNA binds a chromophore-carrying molecule. In either case, chromophore-labeled duplexes are excited by light of the proper wavelength and the resulting emission signals are measured by a fluorescence detector. Although detection of a single molecule's fluorescence is theoretically possible, in reality both reader sensitivity and background fluorescence are limiting factors in using fluorescent labels for SBH. Signal detection limits with advanced commercially available readers are approximately 1–10 chromophores per square micrometer. Direct fluorescence has been the labeling method of choice in miniaturized SBH formats, although mass spectrometry is becoming increasingly popular.

6.5 Discriminative Hybridization

6.5.1 Hybrid Stability

SBH is possible because the specificity of binding between single-stranded DNAs and complementary oligonucleotide probes (expressed as binding strength or recognizable duplex structure) can be used to discriminate matched from mismatched probes. The experimental parameters used to influence binding/dissociation generally include hybridization and wash temperatures, wash time, and other solution conditions such as salt concentration (see Wetmur[44] for a more detailed treatment). In the case where one of the strands is attached to a solid support, the dissociation temperature, T_d, at which 50% of duplexes have dissociated is used as a measure of hybrid stability. Figure 5 shows DNA–probe dissociation curves for a typical full-match 8-mer probe and two different single-mismatch 8-mer probes as a function of temperature. The separation of the curves suggests that near T_d for a mismatched probe hybrid, most full-match probes remain bound to the target DNA, allowing discrimination of the two probes.

In general, both thermodynamic and kinetic factors influence the binding and dissociation of DNA–probe hybrids, but it is generally kinetic dissociation rates that are used to discriminate between matched and mismatched probes. In free solution, T_m (the temperature at which 50% of possible duplexes are melted) is a linear function of GC content. T_m may be converted to T_d by a simple equation.[44] In oligonucleotide hybridization, T_m is a more complex function of actual base sequence, and is dependent on ΔG, the standard free energy.[44] For an 8-mer hybrid, ΔG is dependent on three factors: a ΔG sum of nearest-neighbor contributions for seven (of 16 possible) dinucleotide interactions present in the probe, a temperature-independent initiation component, and a dangling end component. Measured values for the various

Figure 5 Dissociation curves of typical 8-mer probes. Graphs represent percentage of denatured hybrid after a 1-min wash at a given temperature. At 15 °C, the fraction of melted hybrids for mismatched probes is two to three times higher than that for full match probes. Probe-DNA hybrids formed with full match probes tolerate higher wash temperatures or longer wash times than mismatched probes, allowing experimental discrimination by manipulating wash temperature and/or wash time.

component contributions have been reported.[45,46] An internal mismatch leads to a decrease in two nearest-neighbor contributions, while an end mismatch results in a decrease of one nearest-neighbor contribution. The stacking interaction of two abutting but noncovalently linked probes hybridized to a longer complementary strand generally has the same effect on stability of the longer probe as lengthening it by one base.[44] Use of this stacking effect in SBH has been proposed by Khrapko et al.[16]

Dangling end contributions are dependent on the single-stranded DNA sequences that surround the DNA–probe duplex, leading to the observation that the same short duplex can have a different stability in different sequence settings.[41] While thermodynamic measurements on synthetic model duplexes generally agree with the theory, no precise prediction of hybridization signal strength has been possible with natural target DNAs. This is due to various sequence context effects on duplex stability or on physical access of probes to binding sites.

Duplex stability (as measured by T_d) decreases with shorter probe length. By manipulating target DNA and probe concentrations one can generally maximize the amounts of remaining duplex product at sub-room temperatures, even for very short probes. The sensitivity of detection provided by radioactive- and fluorescent-labeled probes creates a lower practical limit of approximately 5- to 6-base pair duplexes in SBH. In special conditions, such as ribosome binding sites, stable, base-specific duplex binding occurs in codons consisting of only three base pairs. To improve detection and reduce the number of probes needed for various applications, the use of probes with degenerate ends was proposed for fingerprinting[47] and SBH.[10,11] These are pools of probes that share a common core sequence but have one or more varying bases at the ends. For instance, a complete set of octamer probes with a single degenerate base at each end will exhibit the duplex stability of a decamer probe set. Discrimination is also improved, because all mismatches that occur in the core sequence are internal. Such an 8-mer probe set consists of 65 536 probe pools, as opposed to 1 048 576 possible decamers.

6.5.2 Discriminative Hybridization

Obtaining sufficient matching signal strength over detection background, and at the same time achieving significant discrimination between match and mismatch signals, are critical goals of the probe hybridization process. Drmanac et al.[48] presented a mathematical treatment of the discrimination kinetics of the SBH process that includes the influence of background signal. Using equations describing the association and dissociation of DNA–probe complexes, they showed that optimal discrimination, defined as the ratio of amounts of full-match over mismatched duplexes, is primarily determined by wash temperature and time. Based on their analysis and later experimental verification, they concluded that increases in temperature generally reduce discrimination values (Figure 6). Very low temperatures, on the other hand, require an exponential increase in wash time. The ideal conditions for discrimination of short probes (five–nine bases) were found to be an excess of initial hybrid, moderately low wash temperatures, and extended wash times, usually over 15 min.

Using optimized washing conditions, there are no limits on discrimination values if sufficiently large quantities of hybrid (relative to background) are obtained in the hybridization of large quantities of

Figure 6 Improved discrimination with low-temperature wash. Experimental hybridization images show disproportionate removal of labeled, hybridized probe between full match and mismatch targets as a function of wash time and temperature. To make the phenomenon visually obvious, 50 times more mismatch DNA (M13) is used than full match sample (IF), as shown with control probe in the ''DNA control'' panel. After hybridizing test probe TGCTCATG, and before wash, the M13 signal is still stronger than IF full match signal (''Before wash'' panel). Both samples are then washed at the indicated temperatures and times. At 25 °C, the full match signal is invisible, and the mismatch signal is still detectable after a 2-min wash. The best discrimination is achieved with a long wash at the lowest temperature. At low temperatures the full match signal remains very high (compared to other temperatures), while the mismatch signal approaches background value. The two-fold stronger signal of full match over mismatch targets, combined with the fact that 50-fold more mismatch DNA is used, results in a 100-fold discrimination factor.

target and probe. Figure 6 illustrates 100-fold discrimination achieved in a specially designed test experiment.

There is a thermodynamic explanation for why better discrimination is achieved at lower temperatures and for shorter probes. Discrimination is a function of $\Delta\Delta G$, the difference of ΔGs for matched and single mismatched duplexes. For the same mismatch this parameter is independent of probe length and is inversely proportional to temperature.[45,46] For example, the TGTAC/gGTAC full-match/mismatch 5-mer pair has the same $\Delta\Delta G$ as the TGTACCC/gGTACCC 7-mer pair. Since longer mismatched probes require higher melting temperatures (which reduces the $\Delta\Delta G$ term) such long probes generally exhibit poorer mismatch discrimination than shorter oligomers. For example, T_d values for perfectly matched 14-mer and 20-mers are 41 and 57 °C, respectively,[44] and their dissociation curves would be displaced far to the right of those for the octamers shown in Figure 3. On the other hand, short probes can be hybridized and washed at much lower temperatures, since short mismatch duplexes can be denatured at such low temperatures. At these temperatures, the $\Delta\Delta G$ term is relatively larger, leading to enhanced mismatch discrimination. As a result of these factors the use of two shorter probes instead of a single longer one in Format 3 SBH results in greatly improved discrimination in scoring probes over 10 bases in length.

The basic low-temperature hybridization and washing conditions developed by Drmanac et al.[48] are routinely used in most current SBH applications. These conditions usually involve hybridization at 0–15 °C, using increased concentrations of both probe and target to accommodate the decreased stability of short or AT-rich duplexes. Although 15- to 25-mer oligonucleotides (commonly used in Format 2 SBH applications) can be hybridized at room temperature and above,[7] most Format 2 procedures use low-temperature conditions, primarily to reduce the amount of sample required. Many of the procedures and components used in SBH hybridization and washing are derived from traditional molecular biology hybridization applications.

Format 2 SBH arrays require the simultaneous formation of large numbers of duplexes of different stability. This poses the problem of choosing one optimal temperature (or other hybridization conditions) to maximize discrimination among the many duplex types. To address this situation, Khrapko[16] proposed to measure the differential melting of individual duplexes. This approach is experimentally demanding, and no simple solution to the problem has yet been found. The optimized low-temperature hybridization conditions developed by Drmanac et al.[48] maximize overall discrimination and the number of different duplexes that give measurable signals. Since different signals may be produced by different probe–DNA hybrids, sophisticated scoring systems that recognize more than a single threshold signal are generally used.

While hybrid stability is predominantly used in SBH experiments to detect the presence of complementary sequences in complex nucleic acid mixtures, other means may be applied to achieve mismatch discrimination. Coupling probes using either a chemical agent or ligase (as in Format 3 SBH) is one method of improving discrimination.[19] This procedure transforms short-lived complexes into stable, covalently bound products, producing stronger and more uniform signals even under very stringent hybridization conditions. DNA ligases with increased enzymatic specificity may also be used.[49] Another possibility is to use agents that cut nucleic acid strands at mismatched positions.[50]

7 SEQUENCING BY HYBRIDIZATION AUTOMATION

SBH procedures are generally large-scale analyses that may involve the transfer, storage, and processing of tens of thousands of DNA samples and probes each day. To scale up for such processing, multi-well microtiter plates are used to organize large numbers of dissolved DNA samples or probes. Standard 8 cm × 12 cm plates used in SBH may contain from 96 to 1536 wells. Transfer devices such as robotic pipettors and pin tools are used to create surface-bound arrays or to transfer samples/probes from one plate to another. These transfer devices are arranged in arrays of 8 to 1536 units and can be used to spot samples or probes in arrays on solid supports. The resulting arrays range in size from 100 to 100 000 nucleic acid spots. Electronic bar codes are used to track samples and probes with each transfer step, and to input information in a database. Bar coding eliminates the need for manual recording and tracking and greatly reduces the possibility of labeling error. Figure 7 summarizes the DNA handling and hybridization steps of a typical Format 1 SBH experiment.

Automatic handling of plates containing DNA samples and probes is convenient but not essential, especially when using plates with 384 or more wells. However, high-density plates provide progressively smaller sample volumes (50 μL for a 384-well plate down to 10 μL for a 1536-well plate), which pose potential evaporative loss problems during transfer operations. A variety of techniques have been developed to minimize evaporation and sublimation. These include layering mineral oil over water-based DNA solutions, covering plates with plastic wrap before freezing, and adding glycerol to increase

Figure 7 Format 1 SBH clone analysis procedures. DNA clones are first picked from agar plates and arranged in microtiter plates. Cloned DNAs are amplified by PCR in microtiter plates, then robotically spotted using a pin tool to replica filters, which may contain up to 55 000 DNA spots. Each filter is hybridized with a single probe, then washed and analyzed for signal intensity at all array positions. After scanning, replicate filters are stripped by a rigorous washing procedure to remove labeled probe and re-hybridized with new probes.

viscosity and minimize freezer damage to live cDNA clone cultures.

Arraying more than 100 DNA spots per square centimeter usually involves using tools with precise delivery characteristics mounted on an XYZ robotic station with a consistently repeatable resolution of 10–100 μm. Liquid transfer may be accomplished using a variety of physical principles, including active pipetting by hydrostatic or piezoelectric forces, capillary action, or simple surface tension on the tips of pins. Simple pin tools must be ''reloaded'' after each transfer, while other devices with a reservoir may transfer replicate aliquots of the same sample. Good reproducibility is essential in all arraying procedures, including spot-to-spot transfers from a single channel, channel-to-channel reproducibility within an array, and array-to-array reproducibility. At Hyseq, automated offset printing is used to create a batch of four replicate 55 000-spot arrays on nylon membranes. An 864-pin tool transfers cDNA samples from sixty-four 864-well plates, spotting a few nanoliters of sample with each transfer cycle.[43] This process has been in constant daily operation for over 2 years. Similar procedures are used in many laboratories to create arrays of samples or probes on glass microscope slides.

In situ synthesis of oligonucleotide probe arrays is a computer-controlled photolithographic process in which nucleotides are added sequentially in specific patterns. Specially designed photolithographic masks control the order of light-activated coupling reactions at each array position. This in situ synthesis process may be used to create dense arrays containing over 100 000 probes on a single 1.28 cm^2 substrate.[36–40] Significant amounts of shorter oligonucleotide products are produced as by-products of any long probe synthesis. QC procedures on such arrays are often not practical.

Oligonucleotide hybridization procedures are mechanically simple and are easily automated. Robotic equipment used for hybridization must be able to deliver and remove buffers and sample or probe solutions and a thermostatically controlled heating system is needed to control hybridization temperatures. A method of mixing liquid layers above surface-bound arrays may be used if the overall liquid depth is more than 2 mm. The larger the array, the more demanding the requirements for automation engineering. For example, small numbers of microarrays on glass slides can be processed in simple table-top hybridization devices, while Format 1 arrays containing tens of thousands of samples are processed in large robotic stations. The use of XYZ robotic stations for hybridization procedures allows flexible access to multiple hybridization chambers on a single platform. Drmanac et al.[34] used removable partitions on Format 1 SBH filters to create 384 individual hybridization chambers, each receiving a different labeled oligonucleotide probe for rapid parallel hybridization and washing.

The data readout of an SBH experiment is an array of signals corresponding to hybridization strength at each probe–DNA spot. The image is usually generated by scanning instruments and is composed of rows of pixels. Since each dot is represented by 10 or more pixels, a single large array may contain as many as 10^8 pixels. As described earlier (see section 6.4), owing to the practical limitations on probe and DNA concentrations, scanners must be able to detect between 0.1 and 10 labeled duplexes per square micrometer. Most large SBH applications require high image scanning speed for collection of multiple images per scanner per day. Confocal laser microscopy is generally used to achieve the sensitivity needed for array imaging. For more advanced applications, charge-coupled device (CCD) cameras with 1000×1000 or larger pixel arrays may provide the solution if detection sensitivity of less than 10 labeled duplexes per square micrometer is achieved. Such instruments can acquire multiple images per second, resulting in readouts of over 10^8 pixels per minute.

Future trends in SBH equipment development, particularly in the field of DNA diagnostics, will focus on the design and construction of efficient systems for sample preparation, hybridization, and data readout.

8 DATA ANALYSIS

All current hybridization-based fingerprinting and sequencing applications are based on arrays. The initial data obtained from each unit (DNA or probe spot) in the array is a hybridization signal intensity measured with a detector device. Since individual arrays or sets of arrays may range in size from 1000 up to 1 million array elements, large amounts of primary data must be collected and processed. Automated processing techniques have been developed to handle such large volumes of data. Although user-friendly interfaces have been developed that allow manual intervention in data analysis, the trend in SBH data analysis is to automate the entire process. Information-processing demands of the SBH method can be met by current computer technologies in a cost- and time-efficient manner.

Data analysis consists of four basic tasks, as outlined in Figure 8: (1) sample and probe tracking; (2) image analysis, to transform primary measurements into raw sample/probe responses; (3) normalization and QC of raw data; and (4) analysis of normalized data by application programs to obtain sequence or fingerprint results.

Figure 8 Flowchart of SBH data processing. Hybridization arrays are scanned to capture signal intensity at all array positions, then analyzed using specialized software to locate each array position (image analysis), and to evaluate and normalize signals. Appropriate sample/probe information is collected by a laboratory information management system (LIMS) and stored in the database. Using LIMS, unsatisfactory data are reported to the laboratory for repeated experiments. Normalized signals and LIMS are then used by other computational programs to assemble sequences, map clones, detect mutations and/or identify target DNAs and report results.

The need for precise sample and probe tracking is not specific to SBH applications. Automated laboratory information management systems (LIMSs) have been developed for other genomic and clinical laboratory applications to accurately track sample handling. In Format 1 SBH applications, all microtiter plates, arrays, exposure cassettes, robotic stations, freezers, etc. are bar-coded to allow careful tracking of all sample and probe handling procedures in a central LIMS database. Various programs and user interfaces are used to facilitate both ongoing experimentation as well as proper identification of samples for data analysis. In other SBH formats LIMS procedures are less extensive but still play an important role in data gathering and analysis.

Image analysis for SBH applications has involved the development of specific software packages, since accurate signal processing of spots in predefined arrays (Figure 9) is not a common image analysis application in other technical fields. A pixel image of each hybridized array is generated, with each dot in the array typically represented by 10 to 100 pixels. The first task of SBH image analysis is to define a line grid representing the rows and columns of sample spots in an array. Hybridization images typically do not have positive signals at every unit position in the array. The task of defining this grid becomes progressively more difficult as the percentage of positive spots in the array becomes smaller. Accurately assigning a small percentage of positive spots to an imperfect grid can be accomplished by advanced image analysis programs. Once the grid is accurately established, each spot's signal is quantified by averaging the signals from pixels covering that spot. Intensely positive neighboring spots may create occasional signal spillover, which may need to be corrected to achieve accurate data analysis.

Figure 9 An SBH array image containing 55 000 cDNA spots. Inset shows enlarged region covering approximately 500 DNA samples. Signal intensity is proportional to the amount of bound DNA, the concentration of labeled probe used, numbers of full match and mismatch binding sites, and probe–DNA hybridization strength, which itself is a function of probe length, sequence, and hybridization conditions.

Normalization and QC procedures maintain the quality and statistical integrity of SBH data. Data normalization corrects for experimental variables such as differences in labeling efficiency of different probes or samples, variations in amount of spotted nucleic acids, and other experimental factors. Other normalization procedures measure internal consistency of duplicate data samples, or compare unknown samples and known controls. QC procedures eliminate data that cannot be adequately normalized, or that remain inconsistent after normalization. Also eliminated are data that do not meet empirically measured reproducibility and quality standards. These built-in QC controls help identify and eliminate problem data resulting from misidentified or poorly hybridized samples, probes, and arrays, allowing portions of experiments to be repeated (for more details see Drmanac and Drmanac[43]).

Application-specific data analysis software is developed for each specific combination of data formats and user needs. Owing to the large size of many SBH data sets, obtaining final experimental results is usually computationally intensive, particularly when data elements require pair-wise comparisons. Specific programs capable of extracting results from normalized hybridization data operate on one of two principles: (1) the normalized signal strength is used directly as a measure of the probability of a full match; or (2) the signal is converted into a discrete positive or negative outcome using a function designed for the specific experimental protocol. Owing to limitations associated with each of these approaches, application programs usually combine both methods. In addition, such programs are equipped with statistical routines designed to compensate for certain levels of false-positive and false-negative data.

The inherent redundancies in SBH data can compensate for surprisingly high error rates that may occur in some low-quality data sets. An ''expert system'' type of analysis is implemented to process such complex data sets. In this approach, a decision-making tree is developed to partition data based on signal strength or type of probes, and then to apply different criteria for each subset. For example, hybridization signals may be first divided into strong, weak, or insignificant signals, and then statistical tests used to determine positive and negative probes among the strong and weak signal groups. The nature of SBH data analysis makes it suitable for neural network applications, in which decision-making parameterization is learned by software analysis of data sets with known outcomes. The quality of processing software is measured by its ability to extract all useful information from complex hybridization data sets that contain noise

and error. With proper data analysis, accurate clustering, mapping, and sequencing results are obtained within tolerable error limits. Algorithms for some of these applications are described in section 9.

9 SELECTED STUDIES

In recent years, oligonucleotide hybridization technology has been applied in a variety of important research studies. These include de novo sequencing,[41] gene discovery and fingerprinting,[25] and genetic polymorphism studies.[34] These studies are described in detail below.

9.1 De Novo Sequencing

Drmanac et al.[41] were the first to report successful de novo SBH sequencing. In a blind test, the researchers used both traditional gel methods and SBH to sequence homologous primate T-cell DNA fragments cloned into an 8 kb M13 vector. The similarity of the DNA targets and the occurrence of many single-base mismatches between targets and probes provided a stringent test of the SBH method despite the reduced overall experimental complexity.

In the first stage of this study, one research team sequenced three 2-kb T-cell β loci inserts by traditional sequencing methods. These homologous inserts, derived from human and two rhesus monkey species, were shown to be 92–94% similar in sequence. A second research team used SBH to sequence homologous 116 base pair regions of these clones.

The gel sequencing team constructed a list of 272 octamer probes for determination of the sequences by SBH. The selected probe list contained about twice as many nonmatching as matching probes. The matching probes consisted of all 8-mers with more than three G + C bases or 9-mers with one to two G + C bases that occurred in the 116 base pair DNA segments. To increase the experimental complexity, similar probes corresponding to a fourth primate species (not included as a DNA target) were included in the probe list as well. The SBH research team was informed the list would allow determination of at least one of the sequences and that the other two sequences were similar.

Figure 10 shows representative hybridization images obtained using different 8-mer and 9-mer probes tested against a filter containing 96 DNA samples spotted in duplicate. The filter was prepared directly from M13 phage cultures containing the 116 base pair inserts. Positive and negative DNA controls consisting of M13 DNA were also included, to allow calibration of the hybridization signals for each probe. Pools of sixteen 10- and 11-mer probes containing two degenerate bases as well as the given 8- or 9-mer core were used in these hybridization studies. The longer probes increase hybrid stability and hence signal intensity.

Figure 10 Representative probe hybridizations from a de novo SBH experiment. The same array is hybridized with a mass probe (GCCAGCTTTC, top image) to measure the amount of DNA in all dots, and five specific 8-mer probes. Three test samples are arrayed four times in diagonal pairs. The remaining dots (up to 96) are control samples. Different probes give different combinations of positive and negative results with test samples. Probe GGGCCCAA (second from top) is positive in all samples, and probe ATAAAGAGT (the front or bottom image) is positive only in the third sample. The other three probes in top to bottom order are: CGTGGCCT, GCTGGCCT, TGAGTGTC. The data show clear distinction between positive and negative samples; in most cases the negative samples correspond to a single-mismatch target for the given probe.

DNA filters were first hybridized with a ''mass probe'' specific to the M13 vector, to determine the amount of DNA present in each spot. Each filter was then successively hybridized to a series of test probes. The average discrimination value (defined as the average ratio of signals from hybridization with matched and mismatched targets) obtained for probes in this study was over 10. Figure 10 clearly shows the strong signal intensity and hybridization discrimination obtained from probe hybridizations in this study. The DNA sequences of the three unknown targets were precisely determined after hybridization with only 156 of the 272 probes.

Of the 468 probe hybridization scores obtained in this study, 22 positive signals were observed that were inconsistent with the final reconstructed sequences. In 11 of these cases, the positive signals resulted from full-match hybridizations with the M13 vector. Most of the remainder (seven cases) occurred because of the summation of

signals caused by two or more single-mismatch hybrids. In four cases, positive signals resulted from hybridization with a single mismatch target.

Both SBH and traditional gel methods gave identical results for all target DNAs sequenced in this study. Although the number of probes used was greatly reduced relative to the set of all possible octamers, the similarity of the DNA targets and the many single-base mismatches posed technical challenges comparable to those found in a much larger sequencing project.

9.2 Gene Discovery and Gene Expression

Oligonucleotide hybridization has great potential as an investigative tool in gene discovery studies. The ability to simultaneously process thousands of clones in parallel allows researchers to screen large gene libraries in search of rare or tissue-specific genes.

Gene discovery efforts are based on the concept of identifying gene-specific ''sequence signatures'' for each gene using the hybridization SP (see Figure 1). In gene discovery projects, thousands of cDNAs are spotted to a membrane and then hybridized sequentially to individual probes. Because each n-mer probe binds (on average) once in 4^n bases of target DNA, the set of probes that bind a given cDNA usually provides a unique, sequence-defining ''signature'' for that gene. Identical or closely related cDNAs can be ''clustered'' based on their similar signatures.

In an important early demonstration of gene discovery methods, Drmanac et al.[25] screened 73 536 cDNA clones derived from infant brain libraries. Using 200 to 320 oligomer probes (mainly 7-mers) to hybridize these clones, they identified 19 726 distinct genes and estimated that up to 20 000 additional genes are expressed in the infant brain. Clones from both ordinary and normalized gene libraries were used in the infant brain study. cDNA inserts were amplified directly from bacterial cultures in 96-well plates and then pipetted into 864-well plates. Samples from thirty-six 864-well plates were spotted onto a single 16 cm × 24 cm filter using a Beckman Biomek 1000® robot equipped with an 864-pin tool. Negative control spots (without DNA) were arrayed on each membrane to determine background binding. Selected clones of known sequence were used as positive controls.

The probes selected for the infant brain library study were chosen because they occur frequently in coding regions or otherwise helped distinguish unrelated clones. Probes were ^{33}P labeled and hybridized under short-wash, low-temperature conditions designed to generate a wide range of signal intensities and to allow maximum discrimination of unrelated clones. Signal intensities were measured for each clone–probe pair using a Molecular Dynamics PhosphorImager, and a raw intensity value calculated using a specialized analysis program.

A number of cDNAs were rejected from the data analysis due to insufficient DNA or problems with spotting. Using minimal acceptable standards for amount of DNA spotted and number of successful probe hybridizations per clone, a set of 57 419 cDNA clones was selected for further analysis. Of these, 38 900 were obtained from the ordinary library and 18 519 from the normalized library.

For each clone selected, the hybridization intensities of all probes tested against it are ranked from 1 to 100 and these rankings are used to calculate similarity values (SIMs) with other clones. The SIM for a pair of clones is defined as follows:

$$\mathrm{SIM} = \frac{\sum (S_i/L_i)^2}{N} \quad \text{for } L_i \geq T$$

where S_i and L_i are the smaller and the larger of the two rank scores of the ith probe for a pair of clones, T is a threshold used to eliminate probes that rank low with both clones, and N is the number of probes actually used in the pair-wise comparison. Using statistical considerations, a threshold SIM value of 0.57 was calculated to be the optimal level to distinguish clones within a shared cluster from those that are dissimilar. Observed SIM values range from an average of 0.34 for random, unrelated cDNA clones to 0.71 for cDNAs derived from different PCR preparations of a single clone. Sequences that differ randomly at more than 7% of base positions are likely to result in SIM values less than 0.57 and hence would group in different clusters.

Using the clustering criteria described above, the researchers discovered a number of interesting patterns in the ordinary and normalized gene libraries. As expected, the ordinary library contained much larger clusters than the normalized library. The three largest clusters from the ordinary library contained an average of 339 clones each, while the three largest clusters in the normalized library had an average of 56 members. Using various statistical criteria, the researchers were able to determine that most two-clone clusters represent real groupings rather than random associations. However, false negatives (failure to associate two related clones) were found to occur in about 5% of cases.

ESTs of several clones were compared with GenBank data to determine the likelihood that cluster pairings were inaccurate. In general it was found that clones from a single cluster whose sequences matched GenBank data were either identical or very similar to one another. Even in cases where ESTs from two clones within a single cluster seemed dissimilar the most plausible explanation is that they simply represented nonoverlapping regions of different length clones of a single gene.

The researchers also used a clustering process to examine the expression pattern of mRNAs within the

ordinary brain gene library. Only a few of the 14 010 genes that were expressed in the ordinary (non-normalized) gene library were shown to be responsible for most of the expressed mRNAs within the infant brain. Over 50% of all mRNAs were representatives of the largest 10.8% (1519) of clusters. Nearly 72% of infant brain genes were represented by only a single clone cluster. The average cluster contained 2.4 clones.

In the normalized library, clone abundances of the most commonly expressed genes were typically reduced by 10- to 50-fold relative to the ordinary library. Some genes, however, showed increased expression in the normalized library. Overall, the normalization process reduced the number of clones from the most common gene classes from 29.6% to 5.1% of the total.

One of the most valuable aspects of large-scale fingerprinting projects such as this one is the acquisition of large data sets that allow statistical inference about the population from which they are obtained. Using the number of observed one-, two- and three-clone clusters and assuming an expected binomial distribution, it is possible to predict that a total of at least 40 000 genes are expressed in the infant brain. The current study discovered roughly 19 726 of these, but a much larger clone set would be necessary to capture the complete set of expressed genes. It is predicted that up to 840 000 clones would be necessary to find 99.9% of the genes expressed.

The major advantages of using oligonucleotide hybridization in large gene discovery projects such as the infant brain library study are its ability to:

1. identify and assess genes and cDNA transcript variants that are expressed at low levels;
2. measure differential gene expression between various tissue or cell lines for all genes, without previous knowledge about gene sequence, expression, etc.

The use of very large clone sets greatly enhances the ability to detect rarely expressed cDNAs (due to increased sample sizes), and also improves clustering precision for alternatively spliced messenger variants. Given the low expression of many genes within the human genome and the expected continuum of similar genes within gene families, oligonucleotide technology is likely to be an enormously valuable tool in gene discovery and expression studies.

9.3 Individual Sequencing to Discover Novel Polymorphisms and Mutations

As disease prevention and personalized treatments such as gene therapy become increasingly important medical procedures, there is a growing need for methods that can detect mutations in patient DNA samples. Complete gene sequencing is the best approach to ensure that no mutation will be missed, but gel sequencing methods are slow and costly. On the other hand, SBH is an efficient, cost-effective method of screening large numbers of medically important DNA samples by sequencing for such individual variations.

Drmanac et al.[34] demonstrated the accuracy and speed of using SBH to detect individual mutations by sequencing the medically important p53 gene. In a blind experiment, they used 7-mer probe sets to accurately sequence 12 p53 samples that had a variety of individual mutations, including insertions, deletions, and substitutions. Test samples were generated by in situ mutagenesis of a single p53 clone, with a target mutation rate of one base change per exon. Exons 5–8 and the flanking intron regions were then amplified by PCR to obtain a high concentration of target DNA relative to background genomic DNA.

Amplified DNA was spotted directly to membranes without any further purification, a protocol that could be applied to any DNA sample. Samples were spotted in 8×8 replica arrays (each 6 mm $\times$ 6 mm) on GeneScreen membranes. Eight such membranes were prepared, containing a total of 3072 replica arrays. A metal grid matching the membrane array pattern was prepared, containing 384 isolated hybridization chambers.

The researchers used two probe sets in the p53 study. One set consisted of all 2186 7-mer probes that complement the reference p53 exon amplicons. The second set of 8192 probes consisted of all 7-mers that contain at least four G + T bases. The G – T-rich probes were chosen because empirical data have shown that they hybridize more efficiently than C – A-rich probes. Using only the G – T-rich probes does not result in loss of sequence information because each probe will bind either one DNA strand or its complement. Probes were ^{33}P-labeled and hybridized to DNA arrays under low-temperature short-wash conditions.

After hybridization and washing, images were scanned using a PhosphorImager scanner (Molecular Dynamics, Sunnyvale, CA) and then analyzed using a special software package that assigns a signal intensity score for each DNA dot. Figure 11(a) shows hybridization images for the target DNA samples analyzed in this experiment. Negative control spots were used to measure background signal intensity. The signal intensities for probes positive to the control (normal) samples were used to quantify the amount of DNA contained in each spot. The adjusted signal intensities were then used to form a sample/control (S/C) ratio for each base consisting of the median S/C values of the 7 or 14 probes that cover that base in sequence. The S/C value quantifies the relative binding strengths of probes for the test and control DNAs at that base position.

Figure 11 Mutation discovery. (a) Probe hybridization images used to detect G-to-C substitution in exon 6 of p53 gene mutants. Results of hybridization experiments involving two sets of seven probes covering this site are shown. Top panel: probes complementary to wild type sequence with base G; bottom panel: probes complementary to mutant sequence containing base C. DNA samples corresponding to exons 5, 6, 7, and 8 are spotted in an 8×8 square array. Exon 6 DNA dots are located in the top right quadrant of each square, with normal (wild type) reference DNA in the first row and mutant DNA in the second row. Top panel probes, positive to the reference DNA, show strong hybridization signals with dots 5 through 8 of the first row and negative signals for the mutant sample in dots 5 and 6 of the second row. Bottom panel (mutant) probes show exactly the reverse pattern. The other strong signals visible in various images are two corner markers, additional exon 6 test samples with no mutation, or the remaining three exons. (b) Mutation scanning of p53 gene samples. Median signal ratios of test and control DNA (S/C) for reference positive probes are plotted against base position for two exon 5 samples. For more details see text. Mutated samples contain an insertion of a C at position 122.

The sequencing of gene variants is a two-step process that involves plotting S/C ratios for both probe sets. A plot of S/C values for the probe set positive to the control DNA is called a ''mutation scanning graph'' and is used to detect mutations in test DNA samples. When test and control DNAs are identical in a given region, S/C ratios are expected to be unity. When a mutation occurs in a test DNA, the S/C ratio for the mutation scanning graph tends to drop dramatically due to failure of wild-type probes to hybridize the test DNA.

Figure 11(b) shows a typical mutation scanning graph for a p53 test sample mutated at base position 122 in exon 5. The two curves shown reflect homozygote and heterozygote mutations in test DNAs. When the mutation occurs in both chromosomes (homozygote) S/C ratios tend to drop to less than 0.5; when a mutation occurs in only one chromosome (heterozygote) S/C ratios typically drop to between 0.5 and 0.8. The clear ''opening'' in the curve at base position 122 confirms the occurrence of a mutation. Once a mutation has been detected, a sequence determination graph of median S/C ratios from the larger probe set is used to determine the mutated sequence. In this case, probes specific to the mutated test DNA but not the control provide high S/C signals.

A total of 13.2 kb of p53 DNA (12 samples $\times$ 1.1 kb each) were sequenced with 100% accuracy in this experiment. The most difficult sequence assignments are in regions that contain single-base repeats of six or more nucleotides. When a mutation occurs in one of these regions, only one or two of the seven overlapped probes are not shared by the two sequence variants. In one such case, a small number of longer (9-mer) probes were used to confirm the sequence. In longer direct repeat regions

Table 3 Types of mutations detected in p53 gene in blind SBH tests

e8	14 523	gcacagA to Gggaaga	−

[a] Amplicons corresponding to each of four exons are tested separately.
[b] The base position of the mutation in the p53 gene sequence is indicated using accession number X54156 from Gene Bank as a reference.
[c] The exact type of mutation and its heterozygote or homozygote status are also indicated, with "i" indicating an insertion and "d" a deletion.

it may be preferable to use gel sequencing to confirm the final sequence.

An important advantage of SBH is that multiple, independent reads of both DNA strands help ensure accurate, reproducible sequence determination. Five replicate samples of one p53 gene were amplified and sequenced independently to confirm the reproducibility of the SBH process between runs. The coefficient of variation for median S/C values at mutant sites was below 3% for all cases, which is considered well within standards for most clinical diagnostic studies. Overall, the standard deviation of median S/C values in this study was about 6%. It is estimated that such random variation will result in a median S/C value that falls below the 0.8 threshold roughly once in 2500 bases. In the few cases where such false positives occurred the absence of a corresponding peak in the sequence determination graph was used to rule out the possibility of a real sequence change. In conclusion, the SBH method provided 100% accurate sequence determination for over 13 kb of DNA containing a variety of substitution, deletion, and insertion mutants (Table 3).

10 CONCLUSION

The precise instructions for an organism's development and function are recorded and reproduced in the sequences of genomic DNA or RNA molecules through a self-encoding evolutionary process. This information is expressed in three distinct ways: directly as three-dimensional nucleic acid structures (for example, promoter regions that allow specific interactions with transcription factors) or, by transcription and translation, as RNA or protein molecules. Complex networks of interactions between these three basic types of molecules define spatial/temporal and quantitative aspects of self-control necessary for the organism's development or for responses to environmental changes. To be able to understand the enormous number of interactions that exist in these networks, we need to collect and analyze extremely large sequence data sets. We have argued, for example, that sequencing every human gene in about 1000 individuals and defining about 1 million functional DNA polymorphisms is of critical importance. We believe that SBH will become the technology of choice in such projects.

SBH is a versatile, cost-effective method for obtaining the accurate DNA sequence information that is needed to fully understand the implications of genetic variation. The oligonucleotide hybridization and SBH methods use either complete or partial sets of DNA oligomers to identify complementary sequences contained within a target DNA. A small set of oligomer probes may be used to identify an unknown DNA by obtaining its "fingerprint" or "sequence signature," greatly reducing the workload and cost of large-scale sequencing projects by minimizing the number of redundant clones that are sequenced. Larger probe sets may be used to completely sequence a target gene or to detect all mutations relative to a known reference DNA. The multiple overlapping nature of probe sets used in sequencing studies provides high data redundancy and helps ensure accurate sequence information. The use of robotics and microarray technologies allows the processing of hundreds of thousands of probe–DNA hybridization results per day. In its gene discovery program, Hyseq, Inc., routinely fingerprints over a million cDNA clones per month using a single production line. In the more than 10 years since its conception, SBH has become a critical research method, with applications in almost all aspects of genomics. With the explosive growth of genomics research, medical diagnostics, and pharmacogenomics, the coming decades promise even greater developments in SBH technology and its applications.

ACKNOWLEDGMENTS

We thank Radomir Crkvenjakov for analyses, discussions, and critical readings of the manuscript, and Elizabeth Garnett for her excellent organizational assistance throughout this project and for preparation of tables and figures.

ABBREVIATIONS AND ACRONYMS

A	Adenine
BAC	Bacterial Artificial Chromosome
C	Cytosine
CCD	Charge-coupled Device
EST	Expressed Sequence Tag
G	Guanine

Sequencing procedures are aimed at the determination of sequences of monomer units constituting linear biopolymer molecules. In the particular case of nucleic acids the monomer units are DNA or RNA residues. The present article reviews several sequencing strategies: different approaches (random or systematic sequencing) as well as their combinations giving the best results for long-range sequencing applicable to long and unique DNA fragments, including entire genomes, up to the Homo sapiens *genome size; massive sequencing of relatively short fragments such as RNAs, complementary DNAs (cDNAs), etc.; and comparative sequencing of related DNA fragments originating from various individuals or different species.*

Although particular sequencing approaches may involve different ways of DNA treatment (chemical, enzymatic, or physical), they are all based on the same idea: a labeled molecule is cut to obtain a set of fragments all having one common end, other ends being different owing to the statistical character of the nucleic acid chain cleavage. The fragments obtained are then separated according to their lengths.

The primary structure of nucleic acids is a key not only to physical and chemical properties of the molecules but also to the biological (genetic) information therein, including structures of genes and proteins, the ways of gene regulation and cell response to different signals. This is a great advantage over other physical, chemical, or biological methods of DNA/RNA analysis. However, sequencing in itself is usually insufficient to predict unambiguously the biological properties and functions of the encoded products.

1 INTRODUCTION

The organism stores its genetic information in linear molecules of the genomic DNA and this information can be read using DNA sequencing techniques. The primary structure of any natural DNA molecule harbors not only sequences of proteins and RNAs encoded by genes but also the information on gene regulation. Owing to recent advances in sequencing and cloning techniques, the nucleotide sequences of genes often become available long before the functions of these genes in the organism are established. The possibility to analyze entire genomes of various organisms greatly facilitates the finding and identification of new genes and promotes biological studies.

The Human Genome Project (HGP) was officially started in 1990 to map and sequence the whole human genome and the chromosomes of several model organisms. At present the genomes of several microorganisms and bacteria, as well as some model genomes, are already completely deciphered. HGP is a unique project that is supposed to revolutionize biology and medicine. The high-quality sequence of the human genome will have an unprecedented impact and will always be of great value for basic biology, biomedical research, biotechnology,

and health care. A new era in biology – sequence-based biology – will stimulate the progress in understanding gene–environmental interactions and in the development of highly accurate DNA-based medical diagnostics and therapeutics.

2 BRIEF HISTORY OF NUCLEIC ACID SEQUENCING

The first nucleotide sequence (alanine transport RNA of yeast) was determined in 1965 by Holley et al.[1] using an approach initially developed for proteins and successfully used for insulin sequencing.[2] Improvements of the approach made it possible to sequence RNA genomes, and the first RNA genome of MS-2 phage was deciphered in 1975. The development of DNA sequencing progressed substantially more slowly because DNA molecules are much larger, and at that time no deoxyribonucleases (DNAses) with single-base specificity suitable for enzymatic hydrolysis were known. Study of possible chemical modifications of heterocyclic bases resulted in the chemical cleavage method of Maxam and Gilbert (1977).[3] But only the discovery of restriction endonucleases capable of cutting DNA at specific sites, as well as DNA- and RNA-dependent polymerases, has made a revolutionary breakthrough in DNA sequencing. The development of the primer-extension idea reviewed in detail by Wu[4] has led to the dideoxynucleotide chain-termination method by Sanger et al.[5] who shared the Nobel prize with Gilbert for sequencing.

Bacteriophage ϕX 174 (5386 bp) was the first sequenced by Sanger et al.[6] After this, a number of whole genomes of several viruses and organelles were determined: among them the genome of bacteriophage λ,[7] the 229-kb genome of cytomegalovirus,[8] the 192-kb genome of vaccinia,[9] and others. The whole-genome random sequencing strategy was proposed by Venter et al.[10] and used for sequencing of some microbial genomes. The full-length genomes of *Saccharomyces cerevisiae* and *Escherichia coli* were reported in 1996 and 1997, respectively. Currently, active genome sequencing projects are being implemented on insects and more complicated organisms such as *Drosophila melanogaster* (9% done by the end of 1998), *Caenorhabditis elegans* (80% completed by the end of 1998), mouse (10 000 sequence-tagged sites (STSs) mapped), and *Homo sapiens*.[11]

3 SEQUENCING PRINCIPLES AND TECHNOLOGICAL DEVELOPMENTS

All modern sequencing approaches are based on one and the same idea: labeled DNA is treated chemically or enzymatically to obtain a set of DNA fragments all having one common (identical) end, other ends being different owing to the statistical character of the treatment. The fragments obtained can be separated according to their lengths. The methods of DNA treatment are described below.

3.1 Methods Based on Hydrolysis of DNA (RNA) Molecules

3.1.1 Chemical Modifications Followed by Hydrolysis

The idea proposed by Maxam and Gilbert[3] is illustrated in Figure 1. The DNA fragment is end-labeled and modified by a chemical agent specific for a certain

Figure 1 The principle of Maxam–Gilbert sequencing. PAGE = polyacrylamide gel electrophoresis.

Table 1 Chemical modifying agents

	Base			
	Guanine	Purine	Pyrimidine	Cytidine
DNA sequencing	Dimethyl sulfate	Formic acid	Hydrazine (low salt)	Hydrazine (high salt)
RNA sequencing	Dimethyl sulfate	Diethyl pyro-carbonate (only for adenines)	Hydrazine (low salt)	Hydrazine (high salt)

Scheme 1 Biochemistry of chain termination.

heterocyclic base or a definite type of base (listed in Table 1). The extent of modification is chosen so that finally an average of only one break is introduced in each polynucleotide chain. After this partial and specific modification, amine-catalyzed statistical degradation of the modified chain is performed, and the products of this degradation are separated in polyacrylamide gels. By using four different cleavage reactions, the entire sequence can be read. The Maxam–Gilbert procedure is complicated and difficult to automate, so its application to modern large-scale sequencing is limited. However, it can be used for sequencing of ''problem templates'', studies of DNA–protein interactions (''footprinting'') or DNA structures, and oligonucleotide sequencing. A similar approach was applied to RNA by Peattie.[12]

3.1.2 Digestion with Specific Ribonucleases: RNA Sequencing

Radioactively labeled fragments of RNA can be sequenced using partial splitting by specific ribonucleases (reviewed by Kuchino and Nishimura[13]). A comprehensive list of the ribonucleases used is given below (see section 5.2). The application of ribonucleases (RNAses) is restricted by their rather low specificity. Moreover, the RNA degradation rates differ depending on the type of heterocyclic bases.

3.2 Method Based on Specific Termination of Primer Extension

Another approach called the dideoxynucleotide method was proposed by Sanger et al. in 1977.[5] It is underlain by the ability of DNA polymerase to extend a primer annealed to the template in the presence of four deoxynucleoside triphosphates (dNTPs) – dATP, dCTP, dGTP, and dTTP – one of which is usually radioactively labeled to visualize a newly synthesized chain. The growing chain is terminated by a 2′,3′-dideoxynucleoside triphosphate (ddNTP) that blocks the running DNA synthesis (Scheme 1). In this way the synthesis from a unique primer in the presence of all four dNTPs and one ddNTP yields a population of molecules with common 5′-ends but different 3′-ends, depending on the site where the ddNTP was incorporated. Four separate reactions with different ddNTPs are performed, the size of each resulting fragment being determined by the sequence of the template.

The procedure was initially developed for the large fragment of *Escherichia coli* DNA polymerase I (Klenow fragment) and avian myeloblastosis virus reverse transcriptase.[14] Ideally, a sequencing enzyme should be characterized by high processivity and a high rate of nucleotide incorporation; it should also be free from exonuclease activity and should not discriminate against nucleotide analogs. Working in this direction, Tabor and Richardson[15] introduced a chemically modified derivative of phage T7 DNA polymerase (known also under the commercial name of Sequenase®), which met all these requirements. The method is very efficient, presently allowing up to 800 bp of the sequence to be read in one run. It became a routine procedure and, being easily robotized, it is now practically the only method used for large-scale sequencing (see below).

Wide use of polymerase chain reaction (PCR) amplification and new thermostable DNA polymerases allowed the PCR approach and dideoxy sequencing to be combined. These systems provide the option of using either end-labeled primers or primers with incorporated label (such as dNTP). The high temperature used for PCR helps to circumvent the problem of secondary structures and increases the stringency of primer hybridization. Moreover, the amount of template used for sequencing can be markedly reduced to as little as 4×10^{-15} mol.

3.3 Delimiters Approach

This approach combines the features of both the Sanger and Maxam–Gilbert procedures. It is based on the incorporation of so-called delimiters in the course of PCR

amplification that further determine the sites of chemical or enzymatic degradation. A version of this method using thiophosphate-modified nucleotides (2′-deoxynucleoside 5′-α-[P-thio]-triphosphates) as delimiters was proposed by Nakamaye et al.[16] PCR products in this version are cleaved chemically by 2-iodoethanol or 2,3-epoxy-1-propanol at the sites of thiophosphate incorporation. An essentially analogous but enzymatic approach[17] also uses thiophosphate delimiters incorporated into primer-extension products at specific sites subsequently digested by exonuclease III. This approach seemed promising but had a disadvantage of uneven band intensity due to chemical features of thiophosphates. Porter et al.[18] used boranophosphates (2′-deoxynucleoside 5′-α-[P-borano]-triphosphates) to perform both amplification and direct DNA sequencing of PCR products. The ability of boranophosphates to be incorporated into growing DNA chains during PCR amplification and to block exonuclease activity, combined with their thermostability, provides a tool for direct PCR sequencing, as demonstrated in Figure 2.

Technological developments, mostly aimed at improvement of the chain-termination Sanger sequencing, involve new ways of separating sequencing products, new DNA polymerases, and new nonradioactive labels. Development of more advantageous DNA polymerases through modification of natural enzymes can be illustrated with the following best-known examples: bacteriophage T7 DNA polymerase chemically modified to inactivate 3′-5′ exonuclease activity;[15] amino acid changes in the active site (phenylalanine into tyrosine) of several DNA polymerase I family members, to increase the rate of incorporation of dideoxynucleotides versus deoxynucleotides and to solve the problem of uniform band intensity;[19] truncation of the *Thermus aquaticus* (*Taq*) polymerase I N-terminus;[20] and the substitution of Asn^{543} for Ser^{543} in the large fragment of *Taq* DNA polymerase (Klentaq® DNA polymerase) to prevent pausing during DNA synthesis within template regions of complex structure.[21]

The use of radioactive labels and autoradiographic detection suffers from several limitations. Radioactive isotopes have a short half-life that requires their regular supply, and their storage is potentially hazardous. Moreover, autoradiography is a laborious procedure involving manual manipulations. Great progress was made in sequencing technology in 1987, when radioactive labels were replaced by fluorescent ones that allowed autoradiography to be substituted by laser-induced fluorescence detection, thus making possible the direct reading of electrophoregrams. In 1986 Smith et al.[22] reported the first automated DNA sequencer. They used primers labeled with different fluorescent dyes in four sequencing reactions. In one of the other simplest automated

Figure 2 Directed sequencing with boronated nucleotides. A = adenine, T = thymidine, G = guanine, C = cytidine and dNMP = deoxynucleoside monophosphate. [Reproduced by permission of Oxford University Press from K.W. Porter, J.D. Briley, B.R. Shaw, *Nucleic Acids Res.*, **25**, 1611–1617 (1997).]

sequencers[23] the primer was labeled with tetramethylrhodamine iodoacetamide, the reaction mixture was separated into four parts, and sequence identification was similar to the Sanger technique. To avoid primer labeling, Prober et al.[24] proposed a four-colored sequencer based on the use of fluorescently labeled dideoxynucleotide chain terminators, allowing only one sequencing reaction to be performed instead of four. However, overlapping fluorescent spectra of the dyes used in this approach resulted in generally poor accuracy. Internal labeling with fluorescein–dNTPs was proposed by Voss et al.[25] Three automatic sequencers using this labeling and proposed by Smith et al. were commercialized by Applied Biosystems,

DuPont, and Pharmacia, respectively. The development of new fluorescent labels is in progress, including a new class of energy transfer dyes.[26,27]

Clearly being a step forward over manual sequencing, the automated sequencers also have some limitations. Modern sequencing procedures permit up to 600–800-bp-long sequences to be read in one gel. However, electrophoresis in the rather thick slab gels used earlier had to be run at high currents, with accompanying overheating. More recent slab-gel systems are adjusted to thinner gels, which reduces the separation time.[28] A new invention in this field is electrophoresis in capillary tubes filled with polyacrylamide gel. Efficient cooling of the capillaries allows higher electric fields (up to $400\,V\,cm^{-1}$ compared to $30\,V\,cm^{-1}$ in conventional gels) and provides better resolution of separated DNA fragments.[29] The DNA sequencing by capillary electrophoresis is described in detail in the review by Dovichi.[30] Although capillary electrophoresis does not have crucial advantages over ultrathin slab gels, it has some useful practical features, such as easy replacement of separation medium, easy connection to a microtiter plate, and economy in space at high-throughput sequencing. Moreover, low-viscosity polymers used as the separation medium [e.g. noncross-linked polyacrylamide,[30] polyethylene oxide,[31] or polyethylene glycol[32]] are handy for easy refilling of the capillary tubes.

4 LONG-RANGE GENOMIC DNA SEQUENCING STRATEGY

4.1 Random (Shotgun) Strategy

A random (shotgun) sequencing strategy was first employed by Sanger in the course of bacteriophage λ sequencing in 1982.[7] The strategy was based on sequencing of unselected (random) fragments of DNA and did not need any physical map. The theory of this strategy was put forward by Lander and Waterman,[33] and later was developed further and used by Venter's group to decipher successfully several microbial genomes. A detailed description of the shotgun strategy is given in a review by Fraser and Fleischmann[34] and in their work on sequencing of the *Haemophilus influenzae* genome.[10] The major steps of the strategy are listed in Table 2.

DNA of a genome is sheared, e.g. by extraction with phenol–chloroform, resulting in ~50-kb fragments, followed by sonication or nebulization up to fragment lengths of 1–2 kb. The mixture obtained is blunt-ended by BAL31 nuclease, size-fractionated, and cloned into plasmid (pUC), phagemid (pGEM), or phage (M13) vectors. The use of *E. coli* strains deficient in all re-combinant and restriction functions reduces possible rearrangements during the cloning. A library should not contain overrepresented clones, and it is usually characterized by an average representation of 6- to 8-fold genome coverage. Combining the sequence data obtained

Table 2 Whole-genome sequencing strategy[a]

Stage	Description
1. Random small-insert and large-insert library construction	Shear genomic DNA randomly to ~2 kb and 15–20 kb, respectively
2. Library plating	Verify random nature of library and maximize random selection of small-insert and large-insert clones for template production
3. High-throughput DNA sequencing	Sequence sufficient number of sequence fragments from both ends for 6 × coverage
4. Assembly	Assemble random sequence fragments and identify repeat regions
5. Gap closure	
Physical gaps	Order all contigs (fingerprints, peptide links, λ clones, PCR) and provide templates for closure
Sequence gaps	Complete the genome sequence by primer walking
6. Editing	Inspect the sequence visually and resolve sequence ambiguities, including frameshifts
7. Annotation	Identify and describe all predicted coding regions (putative identifications, starts and stops, role assignments, operons, regulatory regions

into one contiguous sequence is performed using software that simultaneously clusters and combines fragments of the genome using a best-matched strategy. For instance, well-developed TIGR Assembler software has been used for getting full-length microbial genomes.[10] A step of filling gaps is indispensable because, according to Lander and Waterman,[33] the distribution of the gaps within the genome is random. There are two types of gaps: sequence gaps with templates available; and physical gaps breaking links between contigs. Sequence gaps can be filled by primer walking along the template. Missing templates can be obtained either by PCR amplification using all possible primers designed for the ends of each contig or by construction of libraries with longer inserts (in bacteriophage λ or cosmids) covering these gaps. The full-length sequence obtained is checked for possible rearrangements and sequencing accuracy. The final step is identification and annotation of open reading frames (ORFs) by a set of algorithms such as BLAST or BLAZE.

The shotgun strategy is a well-developed, high-throughput, and cost-saving sequencing approach that does not need an ordered set of cosmids. However, it suffers from high (6–12) redundancy. To lower this value, Hoheisel et al.[35] fine-mapped shotgun templates before sequencing to order clones by hybridization with individual DNA fragments. A random library ordered by hybridization was then used for sequence analysis. Apart from lower redundancy, this preselection can add important structural information (e.g. positions and types of repeats). Radelof et al.[36] proposed the hybridization of short oligonucleotides with high-density clone filter grids and demonstrated a twofold decrease in redundancy.

The shotgun approach also demands additional efforts to close gaps. Repetitive elements widespread over the eukaryotic genomes aggravate the problem of mistaken contigs. This challenge will probably be eliminated by further progress in sequencing technologies.

4.2 Directed Sequencing

The final phase of any large-scale sequencing project includes closure of gaps, sequencing of repetitive motifs, etc. and is implemented by directed sequencing, mainly primer walking. In the primer walking procedure specific primers are generated for the sites close to the 3′-ends of a known sequence and used for the following elongation steps and sequencing. The steps of primer design and sequencing are repeated until contigs are fused and both strands are sequenced unambiguously. This scheme was proposed by Strauss et al. in 1986[37] and has been used in several genome projects.

The primer walking approach depends on the availability of inexpensive and reliable oligonucleotide primers. There are a lot of primer design computer programs that automatically suggest primers using a set of well-known criteria, such as features of primer–template interactions [e.g. stability of potential binding sites, especially important for sequencing large inserts in phage P1 artificial chromosome (PAC) or BAC vectors], test for self-complementarity and loop formation, stability of the 3′-terminus, and guanine/cytidine content. Several examples of these programs are OLIGO,[38] Primo,[39] Primer Master,[40] and PRIDE.[41]

The efficiency of the primer walking in manual sequencing is typically about 80% but under optimized conditions of automated DNA sequencing this value can be as high as 95%.[42] The primer walking is characterized by low redundancy (2–3 versus 8–10 in the shotgun approach) and low error level (less than 1% per 500 kb). The accuracy can be improved further by simultaneous walking along both strands using two oppositely directed primers, one to obtain new data and the other to confirm already made reads. The primer walking is of great help in the sequencing of repetitive elements and facilitates integration of individual sequences into contigs. All these data were obtained in the course of systematic sequencing of *S. cerevisiae* chromosome XI in the yeast genome sequencing project.[43]

To avoid the need to synthesize primers for each step of primer walking, Studier[44] proposed sequencing cosmids using libraries of 8-, 9-, and 10-mer oligonucleotide primers. The statistics of priming showed that primer libraries sufficient for determining the sequence of the entire human genome (100 000 cosmids) would be small enough to be prepared and managed. In 1990 Szybalski[45] suggested using a rapid assembly of long specific (modular) primers from short contiguous oligonucleotides taken from a relatively small library containing 4096 hexamers. This idea of a pre-made short oligonucleotide collection was developed further by using oligomers containing 5–7 monomers for constructing modular primers,[46–49] contiguous oligonucleotide components of the primers being either ligated on the template or used without ligation. A necessary pool of short oligonucleotide components additionally can be reduced, e.g. 1200–1400 hexanucleotides is sufficient for primer walking on natural templates, which was substantiated theoretically[50] and further confirmed[51] practically.

Yet another approach to systematic sequencing – the construction of ordered sets of subclones – was first described in 1980.[52] This idea was developed further in creating new methods to produce nested deletions in vitro. Henikoff[53] proposed the generation of nested deletions starting from any fixed point in a cloned DNA fragment using controlled exonuclease III digestion of the template. The resulting linear nested fragments

had common ends corresponding to the 5′-end of the sequencing primer and could be cloned and used for sequencing. There is also an analogous method in which nested deletions are formed by controlled BAL31 nuclease digestion (see Breault et al.[54]). Both procedures are manual and rather laborious; they were widely used before the era of automated sequencing but presently their application is very limited.

An idea to introduce sequencing priming sites throughout the target sequence by bacterial and yeast transposons was elaborated by several research groups. Transposons are inserted into many sites of target DNA cloned in plasmid or phage vectors. The integrated transposons are used to form unique priming sites for the sequencing of adjacent uncharacterized regions. The known DNA tracts within transposons are used as binding sites for sequencing primers. Transpositions are generally made in vivo in bacteria using a donor strain carrying the transposons either within a vector or integrated in the genome. A target of interest is introduced into a transposer host to be hit by transposons. The modified targets are then recovered from the host by genetic selection. To be efficient in sequencing, the transposon technique should meet the following requirements: the transposon should be mobilized easily; selection for transposon insertions into the plasmid and into the target sequence should be efficient, as opposed to the bacterial chromosome; and mapping of the transposition sites should be easy in order to minimize the number of required sequencing reactions. Here are some examples of the transposon systems: γδ;[55] Tn3;[56] Tn5;[57,58] Tn10;[59] AT-2;[60] Ty1.[61] The transposon sequencing approach was applied successfully to the sequencing of repetitive regions and filling the remaining gaps in the nematode *C. elegans* genome sequencing project.[62]

4.3 Combination of Random and Directed Sequencing as the Basic Strategy of the Human Genome Project

The HGP was officially started in 1990 as a 15-year collaborative program of mapping and sequencing of the complete set of human chromosomes (3 Gb). The most widely used approaches to human genome sequencing are currently based on preliminary genetic (genes ordered along a chromosome) and physical (overlapped DNA fragments covering a chromosome) mapping of chromosomes. Three clone libraries of different resolution levels were constructed by separating sheared DNA into fragments of different sizes and then inserting them into vectors capable of being propagated in appropriate hosts (Table 3).

The low-resolution physical map in Figure 3 is a set of overlapped YACs containing unique sites amplified by PCR [so-called STSs introduced by Olson et al.[63]]

Table 3 Clone libraries used for genome mapping and sequencing[a]

Vector	Human DNA insert size range (kb)	Number of clones required to cover the human genome
YAC	100–2000	3000 (1000 kb)
Bacterial artificial chromosome (BAC), PAC	80–350	20 000 (150 kb)
Cosmid	30–45	75 000 (40 kb)
Plasmid	3–10	600 000 (5 kb)
M13 phage	1	3 000 000 (1 kb)

YACs, yeast artificial chromosomes.

or restriction enzyme recognition sites. Cohen et al.[64] described a YAC library of 33 000 clones spanning essentially all human chromosomes. A high-resolution map is made by subcloning YAC inserts into cosmid vectors. Sequencing a cosmid library from both ends provides medium-range linking (about 1 per 10 kb) that spans common repetitive elements. A partially overlapped set of cosmids is then subcloned into M13 vectors and sequenced by a combination of shotgun and primer walking methods.

The accuracy of this approach is high because of high redundancy. However, some limitations still exist:[65] e.g. YAC clones are structurally unstable, which results in rearrangements and deletions; and arrayed repeats present problems for high-resolution mapping.

A novel approach to genomic sequencing that eliminates the stage of prior physical mapping uses BAC clones as a starting point.[65,66] The BAC cloning system (Figure 3) was adapted to maintain genomic fragments 300-kb long, the clones being stable even after 100 generations of serial growth.[67] The BAC-end sequencing strategy originally proposed to accelerate genome sequencing provides markers every 5 kb throughout the genome. These so-called STCs link all BAC clones to each other and, being combined with the fingerprint of each BAC clone, supply BACs of interest with ''seeds''. These ''seed '' BACs can be sequenced by any method. Venter's group believes that such an approach might eliminate the problem of gaps in high-resolution physical mapping.

Moreover, Perkin-Elmer announced a new, fully automated capillary-based sequencer ABI PRISM 3700 characterized by high throughput (~1000 samples per day with 15 min of hands-on operator time). This allowed Venter's group to declare the completion of human genome sequencing in the year 2000.

5 SHORT DNA/RNA SEQUENCING APPROACHES

5.1 Complementary DNA Sequencing

Whole-genome sequencing is becoming a routine though laborious procedure, but gene identification and functional analysis of encoded genes remain problematic. From this point of view, cDNA sequencing is one of the main sources of information. Detailed analysis of new methodologies allowing expressed genes to be identified and differences in their expression levels to be quantitated is presented in reviews by Fraser and Fleischmann[34] and Carulli et al.[68]

5.1.1 Expressed Sequence Tags and Serial Analysis of Gene Expression

Expressed sequence tags (ESTs) and serial analysis of gene expression (SAGE) provide a rapid and efficient method of searching for new genes and identification of the coding regions within gene sequences, as well as studying differential gene expression in a variety of normal, developmental, and affected tissues. The EST approach[69] first appeared in the work of Venter's group on the identification of new human genes expressed in brain, and later was applied successfully to many other tissues (liver, heart, testis, pancreatic islet cells, etc.): a comprehensive list of references is given in a review by Fraser and Fleischmann.[34] The SAGE methodology was developed by Velculescu et al.,[70] who analyzed the messenger RNA (mRNA) from human pancreas. The technique allows one to measure the transcript abundance based on the position and content of small sequence tags. Recent examples of SAGE application are the cataloging of ESTs expressed in skeletal muscle,[71] the identification of genes differentially expressed after activation of human arterial endothelial cells,[72] and the analysis of transcripts in non-small cell lung cancer.[73]

The EST and SAGE methodologies complement each other in providing sequence tags for the identification of genes. Development of further modifications of genome-wide gene analysis combining both EST and SAGE[74] is under way. Being widely used, the EST and SAGE methodologies are not free from some limitations. In particular, both of them can be applied only to eukaryotic organisms with polyadenylated mRNAs. Accurate quantitative data of EST analysis depend on large-scale sequencing, which implies the availability of sequencing facilities. The classic SAGE requires relatively high amounts of input RNA, so it is inapplicable when RNA amounts are limited. However, a micro-SAGE modification of the method proposed by Datson et al.[75] works successfully with 500–5000-fold less starting material.

5.1.2 Differential Display

The differential display technique first developed by Liang and Pardee[76] is PCR-based and provides data on gene expression. This method uses a set of small random primers to amplify partial cDNAs from subsets of mRNAs. The resulting labeled short sequences are separated in sequencing gels; samples running in parallel show differences in mRNA compositions. The separated labeled tags are isolated from the gel and sequenced. This technique does not require knowledge of the genome context, but it requires extensive follow-up work and is relatively slow.

5.1.3 Complementary DNA Microarray Analysis and DNA Chips

These hybridization techniques, as alternatives to direct cDNA sequencing, are fast, accurate, and cheap. Providing that the genome context is known and using the recently developed high-density gridding technique, DNA microarrays can represent every individual ORF from a particular organism and provide a true global pattern of the gene expression under various conditions.

5.2 RNA Sequencing

RNA is sequenced according to the general principles given in section 3.

5.2.1 Chemical Degradation

Four different base-specific chemical reactions were proposed for partial and specific digestion of end-labeled RNA.[12] Strand breaks at the sites of the chemical attack generate a nested set of labeled fragments that are resolved by electrophoresis. The modifying reagents are presented in Table 1. Kochetkov et al.[77] introduced an improved uridine-specific modification, later used by Waldmann et al.[78] Solid-phase modifications of the chemical RNA sequencing were described. In this case the reactions are carried out on Whatman DE 81 anion-exchange paper[79] or DEAE-cellulose sheets[80] as support. The base-specific chemical cleavage for RNA sequencing is a powerful technique that is largely insensitive to secondary structure. Unfortunately, the procedure is time-consuming and its application is limited at present.

5.2.2 Enzymatic Degradation

Ribonucleases used for RNA sequencing are given in Table 4. All these endonucleases are single-strand-specific. A feature of RNA as compared to DNA is the more complex secondary structure, often hindering enzymatic hydrolysis. Kisselev et al.[86] proposed a complete and selective modification of cytidilic residues by methoxyamine–bisulfite mixtures that leads to RNA unfolding. This helps to generate a more uniform set of fragments after RNAse treatment. The $C^{modified}$–N bond is easily digested by T2 and A RNAses.

5.2.3 Primer Extension

The general principle of specific termination of newly synthesized polynucleotide chains proposed by Sanger[5] and adapted for RNA remains a dominant approach in RNA sequencing. The first chain-terminating RNA sequencing was demonstrated by Kramer and Mills,[87] who used RNA-dependent RNA polymerase (Qβ-replicase) and 3′-deoxyribonucleoside 5′[α-^{32}P]-triphosphates as specific chain-terminating ribonucleotide analogs. Another RNA polymerase[88] (SP6 polymerase) as well as other terminating ribonucleotide analogs[89] (3′-*O*-methylnucleoside 5′-triphosphates) were also tested for sequencing.

Nevertheless, RNA-dependent DNA polymerases (reverse transcriptases) introduced by Brownlee and Cartwright[90] are used preferentially (for a review, see Hahn et al.[91]). The procedures for making use of reverse transcriptases from avian myeloblastosis virus and Moloney murine leukemia virus are developed in detail.[92,93] These methods work equally well with all kinds of labeling, be it labeled α-dNTPs, labeled primers,[94] or fluorescently labeled ddNTPs.[95] The latter type of labeling minimizes unspecific chain-termination events and is adapted for automated sequencing. Other possible ways to avoid premature chain termination are treatment of RNA templates with methyl mercury[96] and reverse transcription at higher temperatures.[97]

A review of mass spectroscopic RNA sequencing methods can be found in section 5.3.

Table 4 Ribonucleases used for RNA sequencing

Ribonuclease	Specificity	Comments
T2	Unspecific	For statistical cleavage
T1[82]	Guanosine	
U2[82]	Adenine > guanosine	Proposed special conditions for specific cleavage adenosine-3′-phosphate ↓ N
A[82]	Uridine + cytidine	Cleavage rates differ greatly: pyrimidine ↓ purine ≫ pyrimidine ↓ pyrimidine
Phy1 (from *Physarum polycephalum*)[83]	Distinguishes between cytidine and uridine	Strong preference for N−cytidine over N−uridine uridine−N over cytidine−N
Bc (from *Bacillus cereus*)	Uridine + cytidine	Pyrimidine residues
Staphylococcus aureus nuclease[84]	Uridine + cytidine	Pyrimidine−N at pH 3.5 without Ca^{2+} N−uridine and N−adenine at pH 7.5 in Ca^{2+}
M1 nuclease (from *Cucumis melo*)[85]	N ↓ adenine, N ↓ uridine, N ↓ guanosine	Stable in 7 M urea
Ribonuclease CL3 (chicken liver)[86]	Cytidine	

5.3 New Approaches

5.3.1 Mass Spectrometry

Mass spectrometry (MS) is one of the unconventional approaches ranging between simple replacement of a fluorescent detector in gel electrophoresis with a mass spectrometric detector and attempts to sequence a single DNA molecule in an ion trap. Matrix-assisted laser desorption and ionization (MALDI) was first proposed for the sequencing of large proteins up to 300 000 Da,[98,99] but in a technically improved form it is now applied also to the sequencing of nucleic acids.[100,101] The most promising approach is to replace electrophoretic separation of nested DNA (RNA) fragments obtained by the traditional Sanger technique, chemical or enzymatic cleavage with mass spectrometric separation and detection.[102] Cantor et al.[103] suggested a new and potentially high-throughput DNA sequencing approach that uses immobilized duplex probes with five-base-long single-stranded overhangs to bind DNA templates serving as primers for Sanger sequencing. In early studies the sequencing of DNA by MALDI was limited to very short oligonucleotides owing to fragmentation of longer chains during a laser desorption step. Recently introduced matrices[100,104] have allowed the reliable sequencing of longer DNA fragments of approximately 100–130 nucleotides in length.[101]

Matrix-assisted laser desorption and ionization/mass spectrometry (MALDI/MS) relies on a sample preparation in which the analyzed substance (analyte) is co-crystallized with an excess of a matrix, usually an organic acid. The analyte–matrix mixture is desorbed/ionized by a short laser pulse; the generated ions are all accelerated to the same energy in the electric field and subsequently separated in a field-free drift region according to their mass-to-charge ratio. Sequencing data relying on the absolute molecular mass information rather than on relative gel electrophoretic mobility significantly increase the fidelity of sequencing. Other obvious advantages are fast sequence determination and use of unlabeled primers.

In spite of successful sequencing of rather long DNA stretches (about 500 bp), the main MALDI application is comparative (diagnostic) DNA sequencing and re-sequencing or detection of mutations, because the DNA to be re-sequenced is usually not very large. Unambiguous detection of polymorphic sequences has been demonstrated in both homozygous and heterozygous samples.[105]

5.3.2 Scanning Tunneling Microscopy

Scanning tunneling microscopy (STM) was used to visualize duplex DNA at atomic resolution.[106] Experimental STM profiles showed a double-helical structure, base pairs, atomic-scale substructure, and excellent correlation

Figure 4 Pyrosequencing method. PP_i = inorganic pyrophosphate; dXTP = one of the four deoxynucleoside-5′-triphosphates. [Reproduced with permission from M. Ronaghi, M. Uhlen, P. Nyren, *Science*, **281**, 363–365 (1998). Copyright 1998 American Association for the Advancement of Science.]

with atomic contours of the Van der Waals surface of DNA. Since 1990, no additional information on this approach has appeared.

5.3.3 Pyrosequencing

A novel sequencing approach[107] involves coupled enzymatic reactions to monitor the release of inorganic pyrophosphate (PP_i) during the DNA polymerase reaction (Figure 4). An oligonucleotide primer is hybridized to a template, and sequencing is carried out by a stepwise elongation of the primer strand upon successive addition of four different dNTPs in the presence of DNA polymerase, ATP sulfurylase, firefly luciferase, and apyrase (nucleotide-degrading enzyme). The synthesis of DNA is accompanied by an immediately monitored release of PP_i in an amount equivalent to that of the incorporated dNTP. The intensity of light emitted in the luciferase-catalyzed reaction can be measured readily with a suitable light-sensitive device (e.g. a luminometer). dNTPs not incorporated are degraded by apyrase. This technique is advantageous in terms of accuracy, flexibility, parallel processing, and automation. Moreover, it makes the use of labeled primers, labeled nucleotides, and electrophoresis unnecessary. Another important advantage is the absence of the compression effect due to the secondary structure of the template. The problem of determining the number of incorporated nucleotides in homopolymer tracks, which stems from nonlinear light response, still exists but according to the authors can be compensated for by using certain software algorithms.

5.3.4 Sequencing by Hybridization

The sequence information is obtained here by the hybridization of small probes to a target to be sequenced. Two formats have been proposed. In format I DNA targets are bound to a substrate as a replica array and each replica is hybridized with every possible oligonucleotide probe added in solution. Up to 10 000 clones can be hybridized simultaneously on one membrane. This format was first successfully tested in a blind sequencing of three DNA fragments each of 343 bp in length.[108] In 1998, Drmanac's group reported sequencing by hybridization (SBH) of 1.1-kb DNA fragments.[109] However, in the case of octanucleotide probes as many as 65 000 hybridizations are required, which makes this format too laborious. In an alternative approach (format II) large arrays of oligonucleotides on a solid support are hybridized to a labeled target sequence. Details of format II are given in reviews by Southern[110] and O'Donnell-Maloney et al.,[111] where the techniques of oligonucleotide arrays preparation, possible support material (surface-modified glass, polypropylene, glass with small patches of activated polyacrylamide, etc.), and different schemes of data collection and processing are discussed. All the applications of oligonucleotide arrays are underlain by specific base pairing and include comparing sequences/detecting mutations (see section 6.1) and sequencing per se. The theory of the latter is based on the possibility of distinguishing between perfect and imperfect duplexes and reconstructing the sequence of a target nucleic acid from the corresponding set of oligonucleotides hybridized with it. The maximum length of the analyzed target is roughly equal to the square root of the number of oligonucleotides in the array (e.g. to sequence a 200-bp fragment, an array of 65 536 octanucleotides is needed). The length of oligonucleotides can also be a critical factor. The attempts to use hexanucleotide arrays[114] were of limited success because short duplexes are stable enough only under nonstringent conditions (at high salt and/or low temperatures), which can cause false hybridization signals or even prevent hybridization owing to internal base pairing in the target. Therefore, the use of longer oligonucleotides is preferable but the arrays become too large for existing production methods. Most of the suggested arrays are prepared from octa- and nanomers. The theory of SBH and the accompanying software is being developed.[115,116]

There are only a few known examples of successful direct SBH, but a combination of SBH and gel-sequencing techniques is promising for large-scale sequencing.

A major disadvantage of SBH is ambiguous reconstruction of DNA sequences due to the presence of various repeats within long DNA fragments. Mirzabekov et al.[117] supplemented the SBH procedure with the measurement of distances between certain sites (e.g.

restriction sites or PCR priming sites), which eliminated the problem of repetitive elements.

Another SBH feature is a strong dependence on base composition. An enhanced version of SBH, termed positional sequencing by hybridization (PSBH), was proposed by Broude et al.[118] It uses immobilized duplex probes with single-stranded 3′ overhangs, which pick their perfectly matched DNA targets out of a mixture of different single-stranded DNAs. Ligation of a single-stranded target hybridized to its complementary counterpart in a duplex probe improves the differentiation of perfectly matched targets from those containing mismatches. The use of PSBH in combination with standard solid-state Sanger sequencing without ligation was demonstrated.[119] As little as five bases of known terminal sequence is sufficient for priming.

6 COMPARATIVE SEQUENCING

6.1 DNA Chips

Possible applications of SBH include physical mapping of overlapped DNA clones, gene expression monitoring, identification of microorganisms, and thermodynamic analysis of DNA duplexes. Oligonucleotide arrays are characterized by a wide range of comparative (diagnostic) applications, such as screening of sequence polymorphism and detection of mutations, HLA allotyping, genetic identification, and revealing of genetic variations. Several examples are given in the work by Hacia et al.[120]

6.1.1 Detecting Mutations

High-density arrays have been used to screen 3.4-kb exon 11 of the human breast and ovarian cancer gene (BRCA 1) for all possible heterozygous polymorphisms and mutations. An evolutionary sequence comparison of human BRCA exon 11 and its orthologs in closely related species was done. A 2.3-Mb length of the human genomic DNA was examined by a combination of SBH and gel-based sequencing. Based on SBH pilot genotyping, chips were constructed to characterize human diversity.

6.1.2 Comparative Sequencing

As shown in model experiments, the use of arrays allows one to digitize hybridization patterns and thus to facilitate their comparison.

6.2 Bioinformatics

A scientific field called ''bioinformatics'' is focusing on the creation of computing systems for collection, refinement, analysis, and storage of information. Two areas of bioinformatics are most pertinent to sequencing:

1. Software that allows full-length sequences to be constructed from sequenced regions. An example is one of the most recent programs described by Parson et al.[121]
2. Comprehensive analysis and comparison of sequences available from databases. Overview of this application was summarized by Sander et al., who provided a creative computing system.[122]

Large-scale genome projects generate a rapidly increasing volume of sequence information. By 1999, the genomes of several model organisms had been sequenced, and the HGP is expected to be finished by the year 2001. However, most of the available sequences are functionally uncharacterized. The research in bioinformatics results in the development of methods for computational characterization of these sequences, and the number of computer programs specialized for various analytical tasks is growing rapidly. The most improved packages of information and software are distributed through web sites of the largest genome centers: Sanger Center, European Bioinformatics Institute (EBI), Centre National de la Recherche Scientifique (CNRS), Max-Plank-Institute in Europe; Washington University, National Center for Biotechnology Information (NCBI) and other institutions in the USA.

ACKNOWLEDGMENTS

The author thanks Professor Eugene Sverdlov and Drs Yuri Lebedev, Maria Kostina and Boris Glotov for fruitful discussions and essential help in manuscript preparation.

ABBREVIATIONS AND ACRONYMS

CNRS	Centre National de la Recherche Scientifique
ddNTP	Dideoxynucleoside Triphosphate
dNMP	Deoxynucleoside Monophosphate
dNTP	Deoxynucleoside Triphosphate
EBI	European Bioinformatics Institute
EST	Expressed Sequence Tag
HGP	Human Genome Project
MALDI	Matrix-assisted Laser Desorption and Ionization
MALDI/MS	Matrix-assisted Laser Desorption and Ionization/Mass Spectrometry
MS	Mass Spectrometry

NCBI	National Center for Biotechnology Information
ORF	Open Reading Frame
PAC	Phage P1 Artificial Chromosome
PAGE	Polyacrylamide Gel Electrophoresis
PCR	Polymerase Chain Reaction
PP_i	Inorganic Pyrophosphate
PSBH	Positional Sequencing by Hybridization
SAGE	Serial Analysis of Gene Expression
SBH	Sequencing by Hybridization
STC	Sequence-tagged Connector
STM	Scanning Tunneling Microscopy
STS	Sequence-tagged Site
YAC	Yeast Artificial Chromosome

1 INTRODUCTION

Ribozymes are a family of RNA molecules which possess various catalytic capabilities.[1–3] The best known ribozymes are the endoribonucleases which are capable of cleaving RNA molecules at specific sequences. This group of ribozymes has tremendous potential for the development of a novel approach for the selective inactivation of specific RNA molecules, including both those derived from pathogenic viruses and those associated with inherited diseases. The underlying theory of this inactivation is that the mRNA encoding a harmful protein would be intercepted and destroyed by the ribozymes before that mRNA is translated. In order to be able to fully exploit the potential of a ribozyme, it is crucial to have a complete understanding of the molecular mechanism of the ribozyme reaction. It has long been known that modification of RNA (ribozyme) structure often results in the alteration of its catalytic properties.

The various methodologies described in this chapter are presented in the order of their requirement for determination of the structure/function relationship of a ribozyme, beginning with the preparation of the RNA molecules required for the studies. Primary structural information is needed in order to identify potential ribozymes, then secondary and tertiary structural information are required for ribozyme characterization. The procedures described below are written so as to guide an investigator from the initial observation of RNA catalytic activity (a ribozyme discovery) to the deduction of a structural model of the ribozyme.

We use *delta* ribozymes as a model in illustrating the various steps involved in the structural analysis of ribozymes. *Delta* ribozymes were originally identified as a self-cleaving motif located on the single-stranded RNA genome of HDV.[4] The HDV genome is circular and replicates through a rolling circle mechanism involving only RNA intermediates.[5] Replication is initiated by the binding of the host RNA polymerase II to the parental RNA and results in the synthesis of a complementary multimeric copy of the HDV genome (Figure 1). The monomeric HDV genome is then released from this multimer by the catalytic activity of self-cleaving motif. This intramolecular cleavage is an RNA autocatalytic reaction. The RNA sequence responsible for the cleavage is known as the *delta*-cleaving RNA motif, or as the *cis*-acting ribozyme (Figure 1b). Based on subsequent

Figure 1 The discovery and development of *delta* ribozyme from HDV. (a) The single-stranded RNA genome of HDV is produced in a multimeric unit. Its self-cleaving motif is responsible for the release of multiple monomeric copies of the HDV genome, which are then re-circularized. (b) The *delta*-cleaving motif was subsequently identified. (c) From secondary structural analysis, a *trans*-acting *delta* ribozyme was derived by separating the junction between the P1 and P2 stems.

secondary structural information obtained by various investigators,[6–9] this motif has been modified into an intermolecular system (Figure 1c). This so called a *trans*-acting ribozyme system contains both a substrate molecule and an enzyme molecule.

2 HISTORY

RNA catalysis was first identified in the RNA components of both the group I intron by Cech[10] and RNaseP by Altman[11] in the early 1980s. These discoveries marked the first examples of enzymatic catalysis in the absence of any protein. These catalytically active ribonucleic acids were named ribozymes (RNA enzymes). During the past two decades several ribozymes have been identified that possess various catalytic capabilities which enable them to modify the phosphodiester bonds of their substrates. With the development of in vitro selection procedures, RNA molecules which catalyze a spectrum of reactions, for example phosphorylation and ligation, have been identified.[1–3] Without doubt in the decades to come, additional capabilities of ribozymes will be discovered.

3 SYNTHESIS OF RNA FOR RIBOZYME STUDIES

Ribozymes and their substrates can be produced either by in vitro transcription, or by chemical synthesis. The basic requirements and protocols for these two methods are described below.

3.1 In Vitro Transcription

This protocol makes use of enzymatic reactions catalyzed by purified bacteriophage T7 RNA polymerase, which uses DNA as a template. It has been demonstrated that the sequence immediately downstream of the T7 RNA promoter can affect the yield of transcript, and that the initiating nucleotides CCC or CCU give the best yield.[12] Large RNAs are routinely generated by this method. The model substrate of *delta* ribozyme, an oligomer 11 nt long, is also produced by this method (Figure 2a). Due to the propensity of T7 RNA polymerase to add one or two uncoded nucleotides to the 3′-end of the resultant transcripts,[1] the subsequent purification and verification of both the length and the sequence of the transcripts is required (section 5.2). The main limitation of this method is that it cannot be used when specific modifications are required.

3.1.1 Oligonucleotide Templates

A pair of synthetic DNA oligonucleotide templates can be designed so that one contains the complementary sequences of the T7 RNA promoter and the sequence coding for ribozyme or substrate, while the other contains the sequence of the T7 RNA promoter. Prior to the preparation of an in vitro transcription reaction mixture, the two oligonucleotides (500 pmol each) are mixed in diethylene pyrocarbonate (DEPC)-treated water (20 μL) containing 10 mM Tris(hydroxymethyl)aminomethane (Tris)-HCl pH 7.5, 10 mM $MgCl_2$ and 50 mM KCl, heated at 95 °C for 5 min and allowed to cool slowly to 37 °C. The partial duplexes formed then serve as templates for RNA synthesis by T7 RNA polymerase (Figure 2a).

3.1.2 Cloned Templates

The DNA template of *delta* ribozyme was cloned into the plasmid pUC19 using recombinant DNA techniques (section 4.2). The resultant recombinant plasmid containing the ribozyme sequence is then digested so as to either linearize or release the *delta* ribozyme insert. T7 RNA polymerase will use the resultant DNA duplex as a template and produce transcripts extending until the end of the duplex, so called run-off transcription reactions[13] (Figure 2b).

3.1.2.1 Materials and Methods Mix, in a final volume of 100 μL:

DNA template either as a partial duplex (500 pmol) or as a digested cloned template (5 μg)	20 μL

Figure 2 DNA templates for in vitro transcription reactions catalyzed by bateriophage T7 RNA polymerase. (a) The partial duplex formed by two oligonucleotides. The substrate (11 nt) of *delta* ribozyme is illustrated. (b) The double-stranded DNA. The plasmid pUC19 harboring the sequence of *trans* acting *delta* ribozyme is digested with either *Sma*I or *Hin*dIII and the resulting linear DNA is used as a template. RNA and DNA molecules are identified in brackets.

RNAGuard® RNase inhibitor (Pharmacia)	27 units
rNTP (Pharmacia) 10 mM each,	5 μL
Transcription buffer (5×)	20 μL
(400 mM *N*-(2-hydroxyethyl)piperazine-*N*′-ethanesulfonic acid (HEPES)-KOH pH 7.5, 120 mM $MgCl_2$, 10 mM spermidine) dithiothreitol (DTT) (100 mM)	2 μL
Pyrophosphatase (1 unit μL^{-1}, Boehringer Mannheim)	1 μL
Purified T7 RNA polymerase (2 μg μL^{-1})	2 μL

Incubate at 37 °C for 2–4 h. Add 5 μL RQ1 RNase-free DNase (1 unit μL^{-1}, Promega) to eliminate the DNA template, then extract twice with buffered phenol. Add 0.1 volume of 3 M sodium acetate pH 5.2 and 2 volume of ethanol to the aqueous phase. Chill for 15 min at −80 °C and centrifuge at 4 °C for 15 min in a microfuge. Discard the supernatant then add an equal volume of 70% ethanol and repeat the centrifugation step. Dissolve the pellet in 20 μL of DEPC-treated water and add 10 μL of 5× gel loading buffer (95% formamide, 10 mM ethylenediaminetetraactetic acid (EDTA), 0.05% bromophenol blue and 0.05% xylene cyanol). The mixtures are fractionated by denaturing 20% polyacrylamide gel electrophoresis (PAGE, 19 : 1 ratio of acrylamide to bisacrylamide) containing 45 mM Tris-borate pH 7.5, 7 M urea and 1 mM EDTA. The reaction products are visualized by ultraviolet (UV) shadowing, and the bands corresponding to the correct sizes of the ribozymes and substrates cut out, and the transcripts eluted overnight at 4 °C in a solution (200 μL) containing 0.1% SDS and 0.5 M ammonium acetate. The transcripts are then precipitated by the addition of 0.1 volume of 3 M sodium acetate pH 5.2 and 2.2 volume of ethanol. Transcript yield is determined by spectrophotometry at 260 nm. The sequence and size of the RNA products are then verified by RNase digestion (section 5.2).

Scheme 1 Specific modifications of an RNA molecule.[32] (a) Some modifications on the mononucleotide can be on the sugar or the base residue. (b) The phosphodiester backbone can be modified to a phosphothiolate group.

3.2 Chemical Synthesis

RNA molecules can be chemically synthesized in the same fashion as DNA molecules from 3′ to 5′ by taking the advantage of the high chemical reactivity of the 5′-hydroxyl group. It has been reported that the enzymatic activity of the resultant RNA is equivalent to that of RNA derived by transcription methods.[14] Most importantly, chemical synthesis allows the introduction of single-atom substitutions at specific positions in the RNA molecules. There are three major targets for modification in RNAs: the exocyclic base, the sugar, and the internucleotide phosphodiester linkage (Scheme 1). Presently the cost of production is still prohibitive, especially when large RNA molecules are required. An improved method using the solid-phase chemistry is capable of production in the 200 μmol range; however the chemical synthesis of RNAs longer than 45 nt is not advised when 2′-*O*-*t*-butyldimethylsilyl-5′-*O*-DMT-ribonucleosides (tBDMS-amidites) are used, and of not more than 90 nt when 2′-*O*-triisopropylsilyl-oxymethyl-ribonucleosides (TOM-amidites) are used.[16] In some cases where longer RNA molecules are required, the investigator might combine T7 transcription and chemical synthesis (section 3.3) in order to produce the desired RNA.

An automated DNA/RNA synthesizer (for example, ABI Model 392 or 394 from Applied Biosystem, Foster City, CA) and high-performance liquid chromatography (HPLC) system are required for the synthesis of RNA oligonucleotides using tBDMS-amidites phosphoramidites or TOM-amidites, in addition to nucleoside-functionalized CPG or polystyrene supports (A, G, C, U). Due to the special amidites and deprotection reagents currently available, various modifications can be incorporated into the synthesized RNA. For example, inosine can be introduced at selective bases. 2′-deoxy or 2′-O-methyl RNA can be substituted for the 2′-OH of the ribose residue. The internucleotide phosphodiester bonds can be replaced by phosphothioate or phosphonate linkages. Moreover, other modifications, such as biotinylated RNA and halogenated deoxy and ribonucleotide incorporation, aimed at facilitating the downstream use of the resulting RNAs can also be incorporated.

Due to the high cost of equipment and materials in general, investigators are advised to order custom-made RNA oligonucleotides from facilities such as Keck Oligonucleotide Synthesis Facility (Yale University, CT), and Xeragon AG (Zurich, Switzerland). Following their synthesis RNA oligonucleotides are subjected to deprotection and desalting steps analogous to those for synthetic DNA oligonucleotides. The deprotection removes protecting groups from 2′-hydroxyl of the ribose residue using either TBAF or $Et_3N(HF)_3$ according to the manufacturer's instruction;[15] the subsequent desalting step removes inorganic salts, trace organic compounds, low-molecular-weight impurities and short failure sequences. The latter step can be performed using size-exclusion chromatographic columns such as G-25 Sephadex or reverse phase HPLC.[16] However, gel electrophoresis is the method of choice for removal of failure sequences. The sequence and size of the RNA products are verified by RNase digestion (section 5.2).

3.3 Combination Method

Both enzymatic and chemical techniques can be combined in order to obtain target RNA molecules with site-specific modifications at affordable prices. For example, target RNA molecules with a specific phosphothiolate linkage isomer can be generated by enzymatic ligation of two individual RNAs, one of which is a chemically synthesized RNA containing a phosphothiolate linkage at the desired position. The resultant Sp and Rp isomers are then separated by HPLC. The desired RNA isomer is then joined to the other RNA by T4 RNA ligase.[17] For more examples and details on using a combination of

chemical and enzymatic methods to generate the RNAs of interest, see Vinyak et al.[14]

4 PRIMARY STRUCTURAL INFORMATION

The observation of self-cleaving RNA molecules naturally lead to experiments aimed at identifying the responsible element whether its sequence or surroundings causes the cleavage. In the case of *delta* ribozymes, a linear dimer of the HDV genome was reported to be initially processed into a monomeric RNA when the responsible cDNA was transfected into a monkey kidney cell line.[4] These findings suggested that either HDV RNA has an unusual secondary structure that allows a specific attack by a cellular RNase, or that the HDV RNA has a specific self-cleaving activity. The self-cleaving motif of HDV was mapped on both strands of the HDV genome in order to locate the cleavage position.[6] The steps required for this identification are described below.

4.1 Sequence Mapping and Self-cleaving Activity

In general, cDNA coding for the RNA molecules of interest is generated and cloned into a plasmid for identification using standard recombinant DNA techniques. Exonuclease III, a 3′ to 5′ exonuclease specific for double-stranded DNA carrying either a blunt end, a 5′-overhang, or nick, is commonly used for the construction of unidirectional nested deletion sets from the plasmids. The nested deletion clones can be generated from either end using an appropriate restriction enodonuclease that leaves either a blunt end or 5′-overhang to linearize the DNA, followed by exonuclease III treatment. The sequence of each of the resulting deletions is determined by dideoxynucleotide chain-termination sequencing.[13]

RNA transcripts are then produced by in vitro transcription reactions in the presence of 0.05 mCi [α-^{32}P]GTP, and are purified and subjected to various buffered conditions so as to identify the responsible element. To prove that the self-cleaving activity is solely the result of the RNA transcripts, and not due to RNase or proteins present in the in vitro transcription reaction or cell extracts, the purified primary transcripts are incubated in 50 mM Tris-HCl, pH 8.0 and 10 mM $MgCl_2$ (standard conditions for many ribozyme cleavage assays, including *delta* ribozymes).[6,18] The newly formed products are resolved on denaturing polyacrylamide gels, and are visualized by exposure of the gels to either X-ray films or phosphorImaging™ screens.

Figure 3 Cloning of the *trans*-acting *delta* ribozyme. Four overlapping oligonucleotides were designed so that they encode the entire sequence of *trans*-acting *delta* ribozyme. Following annealing of these four oligonucleotides, the resulting fragment was cloned into *Pst*I/*Hin*dIII-digested pUC19. The resultant clone was verified by dideoxynucleotide sequencing. The restriction endonuclease sites are identified on the double-stranded DNA.

To characterize the biochemical properties of the self-cleaving motif, the cleavage efficiency is determined in various buffer systems (pH 5.0–9.0) containing either monovalent (Na^+, K^+ or NH^{4+}) or divalent ions (Mg^{2+}, Ca^{2+} or Mn^{2+}). The *delta* ribozyme self-cleaving motif located on the HDV genome was found to be able to use either Mg^{2+} or Ca^{2+} as a cofactor for efficient cleavage in Tris-HCl pH 5.0–8.0.[6] The cleavage products were identified as a 3′ fragment with 5′-hydroxyl end, and a 5′ fragment with 2′,3′-cyclic phosphate terminus similar to the products of other ribozyme cleavage reactions.

4.2 Construction of Ribozymes and Their Variants

In order to explore enzymatic properties of a ribozyme, cDNA clones coding for the ribozymes are constructed using recombinant DNA techniques. From the primary structural information (i.e. the sequence and the cleavage site), deoxyoligonucleotides can be designed and synthesized for cloning purposes. The *delta* ribozymes used in our studies were initially constructed using four overlapping oligonucleotides (Figure 3). Several restriction sites were included in order to facilitate the creation of variant ribozymes. For example, ribozyme mutants carrying a single mutation in the P1 stem can be produced by digestion of the plasmid carrying the ribozyme with the restriction endonucleases, *Rsr*II and *Sph*I. Subsequent ligation of this predigested plasmid to new oligonucleotides having the altered sequence flanked by *Rsr*II and *Sph*I sites led to the production of the ribozyme variant.[19]

5 SECONDARY STRUCTURE ANALYSIS

Secondary structural information of RNA molecules is generally considered to be a simplification of what is in fact a three-dimensional complex. RNA secondary structure is predicted using either computer-aided alignment, or experimental data. Both approaches suggest putative base pairs in the three-dimensional structure of the RNA molecule.

5.1 Computer-aided Prediction

RNA secondary structure elucidation is similar to an alignment of protein or nucleic acid sequences, except that the RNA sequence folds back on to itself rather than on to identical or similar bases.[20] The complementary bases, G–C and A–U, form stable base pairs through hydrogen bonds between donor and acceptor sites on the bases, and are known as Watson–Crick base pairs. In addition, the weaker G–U wobble pair can be formed in a skewed fashion. These three types of base pairs are called canonical base pairs. Other base pairs (i.e. G–G or C–C) are called noncanonical base pairs.[21] The prediction of secondary structure can be made either from a single RNA sequence by minimizing the free energy of folding, or from a common folding pattern observed for a family of aligned, homologous RNAs. To calculate the free energy of RNA folding, arbitrary energy profiles are assigned to each individual base pair type and motif.[22] For the past decade, the formulae defined by Turner and his co-investigators have been widely used to define the free energy of stacking of canonical base pairs, hairpin loops, and both interior and bulge loops.[20,22] In general, the secondary structural information obtained using aligned RNA sequences is very valuable because the RNA structure is considered to be conserved to a greater degree than the sequence is. Over a period of sequence drift, the structural similarity might remain essentially the same through the phenomenon known as compensatory base changes, which conserve the base pairs,[22] as is observed in the structures of tRNAs or 5S RNA.

5.2 Nuclease Mapping or Enzymatic RNA Sequencing

Enzymatic RNA sequencing is generally used in both the mapping of RNA secondary structures and in the determination of RNA length. This method takes advantage of the cleavage specificity of a variety of ribonucleases and nucleases (Table 1) that are incubated with the substrate RNA in separate reactions. The reaction mixtures are then fractionated by denaturing gel electrophoresis. The resulting bands are compared to an RNA ladder generated from the same RNA. To determine the length of the RNA, several nucleases can be used (Table 1).

Table 1 Ribonucleases and nucleases that are commercially available, and are commonly used, are listed with their optimal buffer[23]

Nucleases	Cleavage	Buffers (5×)
CV or V1	Prefers double-stranded RNA	125 mM Tris-HCl, pH 7.2
Phy M	Ap↓N and Up↓N	250 mM sodium citrate, pH 5.0
S1	Single-stranded nucleic acid	200 mM sodium acetate, pH 4.5, 1 M NaCl, 50 mM $ZnSO_4$
T1	Single-stranded RNA and Gp↓N	250 mM sodium citrate, pH 5.0
T2	Prefers single-stranded RNA and Ap↓N	250 mM sodium acetate, pH 5.0 250 mM Tris-HCl, pH 7.5
U2	Single-stranded RNA and Ap↓N	50 mM sodium citrate, pH 4.5

5.2.1 Materials and Methods

5.2.1.1 5′-Dephosphorylation of RNAs Mix, in total volume of 10 μL:

RNA purified from in vitro transcription reaction (10 pmol μL^{-1})	2 μL
Calf intestine alkaline phosphatase (Pharmacia)	0.2 unit
1 M Tris-HCl, pH 8.0	5 μL
RNAGuard® RNase inhibitor (Pharmacia)	10 units
DEPC-treated water	

Incubate at 37 °C for 30 min. Extract twice with buffered phenol. Collect the aqueous phase, add 0.1 volume of 3 M sodium acetate pH 5.2 and 2 volume of ethanol. Chill the mixture for 15 min at −80 °C. Centrifuge at 4 °C for 15 min in a microfuge, add an equal volume of 70% ethanol and repeat the centrifugation step. Dissolve the pellet in 20 μL of DEPC-treated water to obtain 1 pmol μL^{-1} of dephosphorylated RNA.

5.2.1.2 5′-End-labeling of Transcripts Mix, in total of 10 μL:

Dephosphorylated RNA (1 pmol μL^{-1})	2 μL
10 × T4 polynucleotide kinase buffer (USB)	1 μL
RNAGuard® RNase inhibitor (Pharmacia)	10 units
γ-^{32}P ATP (Amersham, 10 μCi μL^{-1})	3.2 pmol
T4 polynucleotide kinase (USB)	3 units
DEPC-treated water	

Incubate at 37 °C for 30 min. Add 5 μL of loading buffer (95% formamide, 0.05% bromophenol blue and 0.05% xylene cyanol) and fractionate on a denaturing PAGE. The radioactively labeled RNA band is cut out following exposure of the gel to an X-ray film. The 5′-end-labeled RNA is eluted overnight at 4 °C in a solution (200 μL) containing 0.01% SDS and 0.5 M ammonium acetate.

5.2.1.3 Alkaline Hydrolysis Generation of an RNA Ladder Mix, in total of 5 μL, 5′-end-labeled RNA (50 000 cpm μL^{-1}) in solution containing 50 mM $NaHCO_3$ and 5 mM EDTA. Incubate at 95 °C for 5 min. Add 5 μL of loading buffer (95% formamide, 0.05% bromophenol blue and 0.05% xylene cyanol) and fractionate on a denaturing PAGE gel.

5.2.1.4 Nuclease Assay The specific cleavage by nucleases at the ribose-phosphate backbone are carried out using various buffering conditions as listed in Table 1. Frequently $MgCl_2$ or EDTA is also added in order to obtain conditions corresponding to either native or partially denatured folding. Note that the addition of heavy metal ions should be omitted in assays using RNase T2. Moreover, the optimal time required for the mapping is determined depending on the efficiency of each nuclease.[23] The cleavage reaction mixtures are fractionated on denaturing PAGE gels along with the corresponding RNA ladder.

5.3 Chemical Interference

Chemical reagents interact with the heterocyclic bases, the phosphodiester bonds and the ribose moieties resulting in a modified structure (Table 2). The modified residues are detected by primer extension,[2] except when using Fe (II)-EDTA and imidazoles where primer extension is not required in order to resolve the reaction products. Fe (II)-EDTA generates hydroxyl radicals which nonspecifically interact with nucleic acids. Consequently Fe (II)-EDTA is often used for elucidation of the surface residues of an RNA molecule. These interactions occur at the heterocyclic bases and ribose residues, the latter of which results in strand breaks which are detected following gel fractionation. Imidazole and its conjugates rapidly cleave the phosphodiester bonds located in single-stranded regions whereas those located in double-stranded regions are cleaved much more slowly.[23] For *delta* ribozymes, several research groups have used RNase mapping, chemical interference, and UV-cross-linking procedures to determine *delta* ribozyme structures.[24–26] Three versions of the secondary structure are illustrated in Figure 4. The differences result from the different assay conditions used and from the analysis of the mixed population of *delta* ribozymes present in aqueous solution.

Table 2 Chemical interference[23]

Chemicals	Attack at functional groups
Dimethyl sulfate	Nucleophilic centers of heterocyclic bases
Ethyl nitrourea	Internucleotide phosphates and nucleophilic centers of heterocyclic bases
CMCT	Uridine (N3), guanosine (N1)
Ketoxal	Guanosine in single-stranded regions
DEPC	Purine (N7)
Fe (II)-EDTA	Heterocyclic bases and ribose
Imidazole and conjugates	Phosphodiester bonds

CMCT, 1-cyclohexyl-3-(2-morpholinoethyl)carbodiimide metro-*p*-toluene sulfonate.

Figure 4 The primary and secondary structural information of genomic *delta* ribozymes. (a) The sequence of the genomic *cis*-acting *delta* ribozyme is 88 nt long.[33] (b–d) The secondary structures of *delta* ribozyme as determined by Perrotta and Been (b),[7] Wu et al. (c),[6] and Branch et al. (d).[8]

6 NATIVE OR TERTIARY STRUCTURE ANALYSIS

Using both intramolecular and intermolecular (i.e. with surrounding molecules) interactions, ribozymes adopt their native or tertiary structures and thereby gain their catalytic activity. The surrounding molecules used in the intermolecular interaction are metal ions, proteins and water. Over the last few years there has been considerable progress in our understanding of the kinetics of RNA folding and cleavage due to simultaneous advances in both experimental and theoretical methods.[27] Ribonuclease mapping, chemical interference and mutational analyses have been used to define the possible conformations of various RNA molecules. Most significantly, advanced techniques of crystallography, X-ray diffraction and NMR have determined precisely several RNA structures. Currently, the relationship between structure and function has been most thoroughly studied for the group I intron-derived ribozyme. Several of the approaches used in the study of this large ribozyme have also been applied to smaller ribozymes, the best studied of which are the hammerhead ribozymes. However, in some cases structural information from different methods resulted in discrepancies in the proposed structure–function relationship due to the heterogenous population of ribozyme present in aqueous solution. Kinetic characterization has been used widely in the survey of native structural analysis as it relates to enzymatic activity.

6.1 Cleavage Assay

A cleavage assay is the primary method of demonstrating that a ribozyme has adopted its native structure. Like protein enzymes, cleavage assays can be carried out in buffered solution in the presence of trace amounts of radioactive labeled substrate. The radioactive RNA molecules are either the *cis*- ribozyme (RNA carrying a self-cleaving motif), or the substrate for a *trans*-ribozyme. The cleavage reactions catalyzed by both *cis*- and *trans*-δ-Rz require metal ions as cofactors (i.e. $MgCl_2$, $CaCl_2$ and $MnCl_2$). Denaturing agents such as formamide and urea are sometimes included in the reaction mixture in order to disturb any misfolded molecules and thereby enhance the refolding of the ribozyme–substrate complexes.

6.1.1 Materials and Methods

Mix, in total of 20 μL, either radioactively labeled *cis*-acting ribozyme or radiactively labeled substrate of *trans*-acting ribozyme (ca. 50 000 cpm) in buffered solution containing 50 mM Tris-HCl, pH 7.5–8.0, and 5–50 mM $MgCl_2$. In the cases of *trans*-acting ribozyme, an approximate amount of ribozyme is added. Incubate the reaction for the time required (i.e. 10–30 min). Stop the reaction by adding 5 μL of loading buffer

(b) Rz + S ↔ Rz–S ↔ Rz–P ↔ Rz + P

Figure 5 Kinetic analysis of *trans*-acting *delta* ribozyme. (a) An example of a time course experiment. Trace amounts of 5′-end-labeled substrate were incubated with 100 nM *delta* ribozyme in a solution containing 50 mM Tris-HCl, pH 8.0, 10 mM $MgCl_2$. (b) Simplified kinetic pathway of the cleavage reaction catalyzed by *delta* ribozyme.

(95% formamide, 0.05% bromophenol blue and 0.05% xylene cyanol) and fractionate on a denaturing PAGE (Figure 5a).

6.2 Metal Ion Dependence

In general, ribozymes require the presence of metal ions for their folding and cleavage activity. These metal ions (Mg^{2+}, Ca^{2+}, Mn^{2+}, Sr^{2+} etc.) are added to the cleavage reactions in either the presence or absence of monovalent ions (Na^+, K^+ or NH_4^+) in order to determine the metal ion requirement.

6.3 Kinetic Determination

Time course experiments are performed at various substrate and ribozyme concentrations in order to determine kinetic parameters, such as a maximum rate of cleavage and substrate association constant.

6.3.1 Single Turnover Conditions

Various amounts of ribozyme are mixed with trace amounts of substrate (final concentration < 1 nM) in a 18-μL reaction mixture containing 50 mM Tris-HCl pH 7.5, and are then subjected to denaturation by heating at 95 °C for 2 min. The mixtures are quickly placed on ice for 2 min and equilibrated to 37 °C for 5 min prior to initiation of the reaction. Cleavage is initiated by the addition of $MgCl_2$ to 10 mM final concentration. The cleavage reactions are incubated at 37 °C, and followed for 3.5 h or until the end-point of cleavage is reached. The samples are quenced by the addition of 5 μL stop solution (95% formamide, 10 mM EDTA, 0.05% bromophenol blue and 0.05% xylene cyanol), and are analyzed by 20% PAGE as described above. Both the substrate (11 nt) and the reaction product (4 nt) bands are detected using a molecular dynamic radioanalytic scanner after exposition of the gels to a phosphorImaging™ screen (Figure 4a).

6.3.1.1 Measurement of Pseudo-first-order Rate Constant (k_{cat}, K_M and k_{cat}/K_M) Kinetic analyses are performed under single turnover conditions as described by Hertel et al.[28] with some modifications for *delta* ribozyme. Trace amounts of end-labeled substrate (<1 nM) are cleaved by various ribozyme concentrations (5–500 nM), and the fraction cleaved is determined. The rate of cleavage (k_{obs}) is obtained from the fitting of the data to the equation $A_t = A_\infty(1 - e^{-kt})$, where A_t is the percentage of cleavage at time t, A_∞ is the maximum percent cleavage (or the end-point of cleavage), and k is the rate constant (k_{obs}). Each rate constant should be calculated from at least two measurements. The values of k_{obs} obtained are then plotted as a function of ribozyme concentration in order to determine the other kinetic parameters: k_{cat}, K_M and k_{cat}/K_M.

6.3.2 Multiple Turnover Conditions

Trace amounts of labeled substrate are mixed with unlabeled substrate in order to obtain various substrate final concentrations. Fixed amounts of ribozyme (50 nM) are then added to the substrate mixtures in an 18-μL reaction mixture containing 50 mM Tris-HCl pH 7.5, and then subjected to denaturation by heating at 95 °C for 2 min. Again the mixtures are quickly placed on ice for 2 min and equilibrated to 37 °C for 5 min prior to the initiation of the reaction. Cleavage is again initiated by the addition of $MgCl_2$ to 10 mM.

6.3.3 Inhibition Analysis

The inhibitory effects of the substrate and the product can be kinetically tested under both single- and multiple-turnover conditions.

6.3.3.1 Single Turnover Conditions Conditions similar to those described above can be used with various amounts of potential inhibitors (either substrate, product or oligonucleotide). The reactions are initiated by mixing inhibitors (0.5–20 μM) with substrate (1 nM) prior to addition of the ribozyme (50 nM) in 20 μL enzyme assay buffer (50 mM Tris-HCl pH 8.0, 10 mM $MgCl_2$). Aliquots (2 μl) are withdrawn at various intervals during the 40-min incubation period, and are quenched by the addition of ice-cold stop solution (6 μL). The samples are fractionated on 10% denaturing PAGE gels, and the reaction products are quantified following exposure to phosphorImaging™ screens. Control reactions are carried out in the absence

of inhibitor. To evaluate the effect of an inhibitor on the intrinsic rate of *delta* ribozyme cleavage, the data are analyzed as described by Clouet-d'Orval et al.[29] in order to determine the fraction of inhibition (I) at each inhibitor concentration. Equation (1) is used:

$$I = 1 - \left(\frac{k_{2_{\text{inhibitor}}}}{k_2} \right. \quad (1)$$

where $k_{2_{\text{inhibitor}}}$ and k_2 are the rates of cleavage in the presence and absence of the inhibitor, respectively. The values of k_2 are obtained from fitting the experimental data to the pseudo-first-order rate equation (Equation 2):

$$A_t = A_\infty(1 - e^{k2t}) \quad (2)$$

where A_t is the percentage of product formed at time t, and A_∞ is the maximum amount of product formed. The fraction of inhibition (I) is plotted versus inhibitor concentration, and the data fitted to a hyperbolic equation in order to obtain N_I, the inhibitor concentration needed to reduce the rate of cleavage by one-half.

6.3.3.2 Multiple-turnover or Steady-state Conditions
Various concentrations of substrate are mixed with trace amounts of end-labeled substrate (<1 nM) so that final concentration is between 75 and 500 nM in the reaction mixtures. The reaction mixtures contain substrate, ribozyme (50 nM), and inhibitor (0.5–20 μM), and are performed as described for single-turnover conditions. The cleavage rates (v_i, μM min^{-1}) are determined at various substrate and inhibitor concentrations. Lineweaver-Burk, or reciprocal plots of $1/v_i$ and $1/[S]$ at all inhibitor (I) concentrations, are plotted, and the slopes and intercepts calculated by weighted linear regression analyses.

6.4 Three-dimensional Structural Information

6.4.1 Binding Shift Assay

Nondenaturing electrophoresis is commonly used in resolving the isomers that result from the folding of ribozymes. Moreover, kinetic parameters, such as equilibrium dissociation constant (K_d), the association and dissociation of substrate and product (Figure 5b), can be determined by this assay.[19]

6.4.1.1 Materials and Methods The equilibrium dissociation constants can be determined as follows. Various ribozyme concentrations, ranging from 5 to 600 nM, are individually mixed with trace amounts of end-labeled substrate (<1 nM) in a 9-μL solution containing 50 mM Tris-HCl pH 7.5. This reaction is then heated at 95 °C for 2 min and cooled to 37 °C for 5 min prior to addition of $MgCl_2$ to a final concentration of 10 mM in a manner similar to that of a regular cleavage reaction. The reactions are incubated at 37 °C for 1.5 h, at which point 2 μL of sample loading solution (50% glycerol, 0.025% of each bromophenol blue and xylene cyanol) is added and the resulting mixture electrophoresed through a nondenaturing polyacrylamide gel (20% acrylamide with a 19 : 1 ratio of acrylamide to bisacrylamide, in 45 mM Tris-borate pH 7.5 and 10 mM $MgCl_2$ buffer system). The gels are pre-run at 20 W for 1 h prior to sample loading, while the actual electrophorsis is carried out at 15 W for 4.5 h at room temperature. Quantification of bound and free substrate molecules is performed following exposure of the gels to a phosphorImaging™ screen.

6.4.2 In Vitro *Evolution*

An in vitro selection procedure can be used for the identification of important residues in the structure of *delta* ribozymes.[30] A pool of *trans*-acting ribozymes with sequences that have been randomized are produced from synthetic DNA templates using T7 RNA polymerase. In each selection cycle, the inactive ribozyme–substrate complexes can be separated from the active complexes using a biotinylated substrate against avidin. Using this procedure, the nucleotides essential for maintenance of the activity of *trans*-acting *delta* ribozymes were identified.[30]

6.5 Data Analysis

Delta ribozyme is able to catalyze the cleavage of an 11-mer RNA substrate under both single- and multiple-turnover conditions.[18–19,31] In both cases only small differences in the kinetic parameters are observed in the presence of either magnesium or calcium as cofactor. Under multiple-turnover conditions, the catalytic efficiency of the ribozyme (k_{cat}/K_M) is higher at 37 °C than at 56 °C.[17] The cleavage reaction seems to be limited by the product release step at 37 °C, and by the chemical cleavage step at 56 °C. Substrate inhibition is detected at high concentrations of the 11-mer substrate. The 2′-hydroxyl group adjacent to the scissile phosphate is involved in binding with the ribozyme, while the essential cytosine residue of the J4/2 junction has been shown to contribute to substrate association. The kinetic pathway of *delta* ribozyme is believed to involve a conformational transition step that is essential for the formation of the active ribozyme–substrate complex (Figure 5b).

7 CONCLUSION

In addition to fundamental methods for the ribozyme structural analysis, several advanced protocols are being

developed for determination of the structure–function relationship of ribozymes. For example, X-ray crystallography, nuclear magnetic resonance and in vitro selection of RNA molecules have provided the scientific community with considerable information. We believe that these topics should be reviewed by experts in those particular domains.

This article first summarizes the procedures used in the X-ray crystallographic determination of nucleic acids. The methods used to analyze the results of these determinations are presented, followed by a survey of the highlights of the more than 500 structures determined by these methods since the 1970s.

1 INTRODUCTION AND BACKGROUND

The landmark structure of double-helical DNA was discovered using X-ray diffraction data obtained from natural fibers.[1,2] In fibers, the helices are lined up in two-dimensional arrays. The third dimension is often indeterminate because the sample is heterogeneous in length, the helices do not line up in register if the length of every molecule is the same, or the helices have rotational disorder. Helices give characteristic X-ray diffraction patterns, such as the cross pattern of B-DNA, that make it possible to derive the pitch, rise, and number of residues per turn. The data to parameter ratio is low and therefore structures are determined by creating models and then calculating whether these models match the data. The inherent nature of the method is that one derives averaged structures. By using chemically synthesized samples with defined sequences, it has been possible to determine sequence–structure relationships for DNA and RNA. For example, it has been demonstrated that GC-rich sequences are in the A conformation whereas those that are AC-rich are more likely to assume the B conformation. It has also been possible to discover quaternary structures that have been validated using single-crystal methods. An excellent example is the quadruplex structure of poly G[3] that was first discovered in fibers, and then seen in single-crystals. This unusual structure is thought to be a feature of chromosomal telomeres.[4]

The first determinations of single-crystal structures of nucleic acids were published in the 1970s – significantly later than those of proteins. The main reason for this lag was the lack of pure material in sufficient quantity for crystallization. The crystal structure of tRNA was determined using X-ray methods in 1973[5] and was the first, and for a long time the only, biological RNA whose structure was determined. The ability to synthesize and purify oligonucleotides made it possible to determine their structures. The very first dinucleoside phosphate crystal structures provided a great deal of information about the conformational flexibility of nucleic acids.[6] Then in 1979, the first crystal structure determination of more than a full turn of DNA was published and gave rise to more than two decades of research on nucleic acid fine structure.[7]

In this article we outline the steps involved in sample preparation and structure determination of nucleic acids. At the end we summarize some of the highlights of the more than 500 structures determined using single-crystal X-ray methods.

2 DESCRIPTION OF METHODS IN SINGLE-CRYSTAL WORK

2.1 Sample Preparation

DNA samples are most often chemically synthesized using automated methods. Purification steps usually include the use of reversed-phase high-performance liquid chromatography followed by ion-exchange chromatography. RNA samples with fewer than 20–25 nucleotides can be also synthesized chemically. However, longer sequences require the use of enzymatic methods that involve transcribing the RNA from a DNA template using T7 polymerase.[8–10] These methods, however, do not always produce homogeneous samples and further processing of the sample using ribozymes has been employed.[11,12] Once the sample is made, it is

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

purified using both high-performance and fast protein liquid chromatographic methods. The preparation of RNA requires meticulous laboratory practices in order to ensure that the samples are not degraded by nucleases. This entails the use of autoclaved glassware and very high-quality chemicals. Thus, the preparation of RNA that is both pure and in large enough quantities for crystallization is significantly more difficult than for DNA.

2.2 Crystallization

The single-crystal method requires single, well-formed crystals that diffract well. The optimum size is about 0.2 mm on each side, although it is possible to use even smaller samples with the use of intense radiation sources. Oligonucleotide duplexes are sometimes difficult to crystallize in a form suitable for diffraction because the duplexes form quasi-infinite helices or even fibers. Sometimes an apparently beautiful crystal that looks well formed externally does not diffract at all, presumably because the molecules have not lined up in a lattice or have rotational disorder.

Generally, DNA crystals are grown using the vapor diffusion hanging drop method in which a drop of a solution of DNA is placed on a coverslip that is inverted over a reservoir containing the precipitating agent. The components of the drop usually include spermine, $MgCl_2$, sodium cacodylate, and a low percentage of methylpentanediol (MPD). The reservoir contains a higher percentage of MPD. Crystallization usually occurs within a few days. As shown in Figure 1(a) most DNA structures have been crystallized with MPD; attempts to use other agents have not been very successful.

Crystallization of oligonucleotides of RNA is done using procedures very similar to those used for DNA. Longer sequences of RNA including ribozymes and tRNA have been crystallized using a larger number of conditions than have been successful for DNA. Sparse matrix screens[14–17] have been developed that allow the exploration of a broader range of conditions for RNA crystallization in a manner similar to that which has been employed for proteins. Figure 1(a) and (b) shows that whereas MPD is the universal precipitating agent for DNA, a larger number of precipitating agents have been used for RNA.

2.3 Data Collection

Once a crystal has been obtained, it must be mounted for data collection. For data collection at temperatures between room temperature and freezing, the crystal is put into a sealed capillary with a small amount of mother liquor. Increasingly, however, crystals are flash frozen.[18]

Figure 1 Precipitating agents for (a) DNA with length > 4 and (b) RNA with length > 4. (Data and figures were generated from NDBQuery.[13])

This makes it possible to collect an entire data set from a single-crystal since it will not decay in the X-ray beam.

Once the crystal has been mounted, data are collected. Over the years, the methods for data collection have changed considerably. Whereas in the past data were collected using a sealed tube and a diffractometer, nowadays almost all data are collected using a rotating anode which supplies a more intense source of X-rays and either an image plate or multiwire area detector (Figure 2a–d). Although most nucleic acid crystals do not usually require the use of synchrotron radiation, several structures have been determined using data from these sources. It is expected that as the demand for higher resolution information grows, the use of synchrotron data for these samples will increase. Data for protein–nucleic acid complexes are increasingly being obtained using synchrotron sources because of the improved resolution of the data and because of the possibility of using multiple anomalous dispersion (MAD) phasing for the structure determinations.

The resolution of the data determines how accurate the model of the structure will be. The resolution of DNA structures ranges from 0.9 to 3.25 Å with the average being around 2.2 Å (Figure 3a and b). Given the relatively small size of these molecules, these resolutions are relatively low. RNA structures tend to have even poorer resolutions, which may be because of the presence of many flexible loops.

Figure 2 Data collection systems used in structure determination by year. (a) Diffractometer; (b) area detector/image plate; (c) rotating anode; (d) synchrotron. (Data and figures were generated from NDBQuery.[13])

2.4 Structure Determination

The challenge in X-ray crystallography is to obtain the phases of the reflections. Once the phases have been obtained, electron density maps can be calculated. From these maps one can trace the atomic structure of the model. Very small molecules can be phased using direct methods based on reflection statistics. Nucleic acids are in general too large and their resolution is too low for these methods to be used. The very first DNA and RNA structures were solved using isomorphous replacement methods in which heavy atoms are introduced into the lattice. A popular way to do this is to introduce brominated cytosines or uracils into the sequence. For larger and more globular molecules, heavy metals have been soaked into the crystal. Once these heavy atoms have been located, they are used to phase the reflections. This is the most unambiguous way of directly determining the positions of the atoms and is the least likely to lead to incorrect structures. Once a model has been determined for a particular DNA or RNA type, molecular replacement methods are often used for phase determination. In this method, a model of the structure is rotated and translated in the cell until

Figure 3 Distribution of resolution for oligonucleotides with length > 4. (a) RNA; (b) DNA. (Data and figures were generated from NDBQuery.[13])

the model fits the data. If the model is very good, this method works well and gives reliable results. Although molecular replacement has been used with great success for helical DNA, it is possible to obtain incorrect results because of the hypersymmetry of the helix. Hence it is important to carefully evaluate the results of such determinations.

2.5 Refinement

Nucleic acid structures are refined using programs that fit the model to the experimental reflection data; to reduce the number of variable parameters, geometrical restraints are applied by restraining the bond distances and angles to chemically reasonable values. Careful fitting of the electron density maps is also done with electronic visualization programs such as FRODO[19] or O.[20] Central to the use of these programs is the availability of dictionaries containing standard values for the restraints and descriptions of the topologies of the molecules; the popularity of certain programs for nucleic acid refinement matched the availability of these dictionaries. CORELS[21] which was developed for the refinement of tRNA, was superseded by NUCLSQ,[22] which was an adaptation of PROLSQ[23] for nucleic acids. For a long time, this program was the one of choice. X-PLOR,[24] which was enormously popular for proteins, did not begin to be used extensively for nucleic acids until an appropriate parameter file for the nucleic acid force constants was developed[25] (Figure 4a–c). The use of R_{free} in which the R factor for a subset of reflections is monitored as the model is changed has helped to improve the quality of nucleic acid structures. As the resolution of structures begins to improve to values below 0.8 Å, full matrix least-squares methods will begin to be used and the program SHELX[26] is likely to gain in usage for macromolecules (Figure 5).

For all the nucleic acid structures in the Nucleic Acid Database (NDB),[28] the measure of the fit of the model to data, known as the R-value, ranges from 0.07 to 0.25 and the mean value is about 0.18. Although it would be expected that there would be some correlation between resolution and R-value, there is not. By most criteria, the refinements of nucleic acid structures are very good with few anomalies present.

2.6 Analysis of the Results

Once the structure has been determined, there are a variety of analyses that are done to assess both the quality of the structure and the important structural features. In this section, we present a description of these analyses.

2.6.1 Structure Quality

Quality checks for nucleic acid crystal structures are done when the coordinates are deposited in the NDB, which is a searchable archive of nucleic acid structures. The average deviations of the valence geometry from standard values are calculated. In general, these values are <0.02 Å for the bond distances and $<1.5^\circ$ for the angles. These values are more of an indicator of the applicability of the dictionary that was used for refinement than of the actual quality of the structure. Individual values that deviate more than 4σ

Figure 4 Refinement programs used in structure determination by year. (a) X-PLOR; (b) NUCLSQ; (c) other programs. (Data and figures were generated from NDBQuery.[13])

from these averages are also calculated. Intermolecular contacts within the asymmetric unit and in the unit cell are determined. If there are crystal contacts that are smaller than 2.2 Å, and there are no errors in the cell dimensions, this is an indication that there is a problem in the structure; in general, there are very few instances of these sorts of errors in nucleic acid structures. The chiralities of the asymmetric carbons are also calculated. These types of chirality errors are rarely seen in nucleic acid crystal structures although they have been observed in nuclear magnetic resonance nucleic acid structures.[29] Finally checks are made of the match of the model against the experimental reflection data.[30] The values of these *R*-factors are compared with those reported by the author and in most cases there is little difference between them.

2.6.2 Conformational Analysis

There are seven rotatable bonds in the backbone of nucleic acids (Figure 5) and five in the ribose sugar. The torsion angles for these bonds are different for the three classes of DNA double-helical duplexes: A, B, Z

Figure 5 Rotatable bonds in the conformation of nucleic acids. (Reproduced from H.M. Berman, *Biopolymers*, **44**, 23–44 (1997).[27] Copyright 1997 John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

(Figure 6a–c). The repeating unit for the A and B class of right-handed helices is a mononucleotide and there are subtle but distinct differences in the conformation angles for these building blocks. In A-DNA, the sugar pucker is C3′ endo with a δ value in the gauche + range and the χ angle low anti. In B-DNA, the sugars are closer to C2′ endo with the δ value trans and the χ angle high anti. In Z-DNA left-handed helices, the repeating unit is a dinucleotide having an alternation between syn and anti glycosidic angles as its key feature. The ranges for all the torsion angles in duplex DNA has been established (Figure 7a–c).[32] The ranges for the torsion angles for the other classes of DNA structures and for single stranded RNA molecules have not yet been established but it is likely that they will be significantly broader.

2.6.3 Base Morphology

The base pairs in duplex DNA and RNA are not planar (Figure 8). Indeed, it is common for some pairs to have a large propeller twist so that the base pair of one step can form hydrogen bonds with the base pair of the next step. In addition, there are parameters that describe the relationship of the base pairs in succeeding steps. The step parameters that are most useful in describing nucleic acid structure are roll, twist, and slide. For perfectly canonical B-DNA these values are approximately 0, 36, and 0°, respectively. The values for slide and twist are lower in A-DNA (Table 1). Individual structures can deviate widely from the ideal B- or A-DNA models. In the highly kinked DNA of CAP–DNA complexes, for example, the values of roll and twist deviate significantly. Several different algorithms have been developed to calculate these base morphology parameters.[37,38] All of these programs yield similar results, although some subtle differences do exist. Attempts to develop a sequence-specific code for these parameters have been partially successful; it will not be possible to have a reliable set of values for the base morphology parameters for each of the 10 unique base steps in DNA until high-resolution data are obtained.

2.6.4 Hydration

The very first studies of DNA highlighted the importance of the humidity in determining the molecular conformation. B-DNA occurs in high humidity and A-DNA at lower humidity. The crystal structures of nucleic acids have demonstrated certain hydration patterns including

Figure 6 Canonical helical types of (a) A-DNA; (b) B-DNA; and (c) Z-DNA. (Reprinted from H.M. Berman, A. Gelbin, J. Westbrook, 'Nucleic Acid Crystallography: A View from the Nucleic Acid Database', *Prog. Biophys. Mol. Biol.*, **66**, 255–288 (1996).[31] Copyright 1996, with permission from Elsevier Science.)

Table 1 Average values of the base morphology parameters[a] in DNA and RNA duplexes with resolution 2.0 Å or better and in selected nucleic acid fiber structures[34]

Type	Roll (°)	Slide (Å)	Twist (°)
B-DNA with resolution ≤ 2.0	1.0	−0.05	35.8
B-DNA fiber	1.7	0.5	36.0
A-DNA with resolution ≤ 2.0	7.0	−1.92	31.4
A-DNA fiber	12.4	−1.34	30.1
A-RNA with resolution ≤ 2.0	10.4	−2.02	31.8
A-RNA fiber	8.6	−1.43	31.5

[a] Parameters were computed using CURVES[35] for the crystal structures and CompDNA[36] for the fiber structures.

spines and ribbons of water in B-DNA (Figure 9a and b) and water-mediated bridges between neighboring phosphates in A-DNA. Systematic analyses of the hydration patterns around the duplexes have established that the hydration around the bases is local[41] and each base has a distinctive pattern of directly bound water. The hydration around phosphates is also well described.[32] By including the hydrated building blocks to model specific DNA conformations, the characteristic hydration geometries can be reproduced.

3 SURVEY OF KEY RESULTS

3.1 DNA

All the DNA structures determined thus far have been of synthetic oligonucleotides ranging in length from 2 to 16 nucleotides (Table 2). The largest set contains self-complementary dodecamers, which have been modeled after the first B-DNA structure whose sequence is CGCG-CAATTCGCG. Unlike the canonical structure derived from fiber work, this structure demonstrates unique characteristics for each step in the sequence. For example, the A–T base pairs have high propeller twist and the stretch of A sequence is very straight. The structure also shows an asymmetric bend. This template was used to explore the effects of modifications and mismatches and drugs on the structures of DNA; more than 50 structures of this type have been determined. Virtually all of the dodecamer structures fall into a single-crystal form. The advantage of this is that one can explore a variety of sequence–structure relationships while keeping the packing arrangement constant. A disadvantage is that one can

Figure 9 The hydration patterns observed in B-DNA. The hydrogen bonds are shown as dashed lines. (a) The spine of hydration in the minor groove of d[CGCGAATTCGCG]$_2$ (BDL001).[7] The first shell waters are hydrogen bonded to the purine N3 and pyrimidine O2 atoms and are shown as large spheres. The second shell waters bridge the first shell waters and are shown as small spheres. (b) The double row of waters in the minor groove of d[CCAACGTTGG]$_2$ (BDL019).[39] (Reproduced from H.M. Berman, B. Schneider, in *Oxford Handbook of Nucleic Acid Structure*, ed. S. Neidle, Oxford University Press, Oxford, 295–310, 1999,[40] by permission of Oxford University Press.)

Table 2 Types of nucleic acid structures

(a) Duplexes (as of September 1998)

Structure type	Ranges of length	Number with all Watson–Crick pairs	Number containing modifications	Number containing mismatches	Number containing special features
A-DNA	4–12	95	30	4	3
B-DNA	6–13	143	52	16	20
Z -DNA	2–16	51	28	8	7
A-RNA	2–17	23	3	10	5
DNA–RNA hybrid	6–11	25	4	1	6

(b) Structures with novel features (as of September 1998)

Type	Number
DNA tetramers: guanine quartets	3
DNA tetramers: intercalated cytosines	4
Non-classified DNA and RNA structures	78

(c) Biological RNA structures (as of September 1998)

Type	Number
Ribozymes	8
tRNA	11

(d) Protein–nucleic acid complexes (as of September 1998)

Type	Number
Protein–DNA	256
Protein–RNA	29

never be sure of how much this particular lattice is actually influencing the structure. For the most part, neither simple chemical modifications nor the presence of mismatches create global changes in the DNA. Although the effects are local, they could certainly have profound effects on recognition at the site of the lesion and thus aid in repair.

The more than 30 decamer structures crystallize in a variety of space groups. The crystal packing range from ones in which the helices line up one above the other forming crystals with almost idealized closest packing, to ones in which the major groove of one helix packs against the backbone of another (Figure 10a–d). These structures are in general higher resolution and again provided a fertile template for the understanding of DNA fine structure. The results of studies on B-DNA structure have been reviewed elsewhere.[27,46]

Figure 10 Packing motifs in DNA duplexes in B- and A-DNA. (a) Minor groove–minor groove interactions in BDL042;[42] (b) Major groove–backbone interactions in BDJ060;[43] (c) stacking interactions in BDJ025;[44] (d) terminal base pair–minor groove interaction in ADJ049.[45] The bases are color coded: (green = guanine; yellow = cytosine; red = adenine; blue = thymine). (Reprinted from H.M. Berman, A. Gelbin, J. Westbrook, 'Nucleic Acid Crystallography: A View from the Nucleic Acid Database', *Prog. Biophys. Mol. Biol.*, **66**, 255–288 (1996).[31] Copyright 1996, with permission from Elsevier Science.)

Figure 11 Some examples of crystalline DNA. (a) B-DNA with a drug bound in the minor groove, GDLB05;[49] (b) DNA with intercalated drugs, DDF019;[50] (c) tetraplex DNA with G quartets, UDF062;[51] (d) B-DNA containing a bulge, UDM010.[52] The bases are color coded: green = guanine; yellow = cytosine; red = adenine; blue = thymine; other residues and drugs are black [except in (c), which is colored by strand].

The dodecamer and decamer structures are amenable to the binding of drugs in the minor groove, making it possible to gain insight into molecular recognition. More than 40 structures have been determined in which the drug nestles into the minor groove. In some cases, the drugs bind in pairs. There are also several examples of intercalating drugs such as daunomycin and actinomycin whose planar groups fit between two base pairs and cause the DNA to unwind. Both of these drugs also have prosthetic groups that further interact with the DNA.

A-DNA structures have also been extensively studied and reviewed.[47] In general there are greater variations in the helices, probably because of packing effects. The packing of these molecules is very characteristic with the minor groove of one duplex butting up against the phosphate backbone of another.

One of the most surprising results of the explorations of DNA structure was the discovery of the left-handed Z-DNA [for a review, see Ho and Mooers[48]], which exists in solutions containing very high salt or alcohol

Figure 12 Some examples of RNA structures. (a) A-RNA duplex with internal loops, ARL037[55] (top) and Watson–Crick base-paired A-RNA, ARN035[56] (bottom); (b) a hammerhead ribozyme, URX035;[57] (c) yeast phe tRNA, TRNA04;[58] (d) a group I ribozyme domain, URX053.[59]

levels. The correlates of this conformation in crystal form are the presence of alternating pyrimidine and purine sequences and a strand length of six. Almost all the Z-DNA structures pack with the helices lined up one atop the other.

DNA can also form quaduplexes (Figure 11a–d). Two different types have been observed. In one type the guanines form quartets [e.g. UDF036[53]]. In the other cytosines from two strands intercalate between cytosines of the other two strands [e.g. UDD023[54]].

Within these major classes of DNA structures, many special features have been observed. These include bulges caused by extra bases in one strand, frayed ends or single base overhangs. These latter features enable the ends of the DNA molecules to associate in novel ways forming for example triplets. Interestingly, the one major structural type that has never been observed in crystals is the DNA triple helix.

3.2 RNA

The very first oligonucleotide structures to be determined were RNA dinucleoside phosphates and for a long time these were the only oligomers studied using X-ray methods. With the availability of methods to prepare, purify, and crystallize RNA, increasing numbers of RNA structures are appearing.

Duplexes of RNA with Watson–Crick base pairing have been crystallized; these have the expected A conformation (Figure 12a–d). In some of these cases, sequences were crystallized in order to model RNA hairpin stem-loops; instead, A-type helices were seen in the crystal.[55] To accomplish this, these helices have stretches of mismatches that form internal loops. Furthermore, the mismatches seen are not simply ones involving the bases themselves but also utilize water molecules. A summary of the types of mismatches and internal loops is given elsewhere.[60]

Two classes of biological RNA molecules have been crystallized: tRNAs[61] and ribozymes.[57] The tRNA molecules are single stranded molecules in which a cloverleaf type secondary structure folds into an L-shaped molecule with extensive base stacking and tertiary hydrogen bonds. These hydrogen bonds form between conserved bases and thus are key structural elements in all tRNA molecules. The structures of hammerhead ribozymes, like the structures of tRNA, have extensive base stacking and exhibit some of the same unusual conformation and hydrogen bonding features. The structures of both tRNA and the hammerhead ribozyme have provided testable models for understanding their biological functions. Base stacking, tertiary hydrogen bonding interactions, and more conformational motifs also dominate the spectacular structure of the P4–P6 domain of the group 1 intron ribozyme.[59] Although it is certain that there will be more RNA structural elements forthcoming, it should now be possible to classify systematically those that have been seen thus far in order to facilitate modeling of larger RNA structures.

4 CHALLENGES FOR THE FUTURE

Although many structures have been determined, there are still many unanswered questions. In the field of DNA crystallography, the issue of how much the sequence determines the structure is as yet unknown. To be able to understand this, it will be necessary to determine the structures of the same sequences in different crystalline environments. The effects of complexation to proteins and drugs can only be answered by studying sequences alone and in complexes. Further, of course, in dealing with the level of fine structure inherent in defining base morphology, there is a clear need for very high-resolution structures. RNA crystallography is still in its infant stage, and when fully developed it will allow us to understand more fully the complex rules that govern the folding of single strands into compact structures.

1 INTRODUCTION

Surveys have shown that in the 1980s the production of powdered materials had an annual value in excess of US$10 billion,[1] while more recent surveys showed that an estimated 25–30% of the total output value from the chemical industries was in the physical form of either powdered or agglomerated material.[2–4] There is now an awareness, within many sections of the chemical industry, to the increasing amount of bulk powdered materials – in the form of crystalline solids, agglomerated or granulated powders, and processed or comminuted powdered materials – that are being produced year by year. The characterization of the particulate material produced – together with the handling and behavior of powdered material in bulk quantities – is therefore of paramount importance in the optimization of many multiphasic and multiparticulate processes. The variations in the behavior and dynamics of various types of processing, due to the presence of particulate material and the formation and generation of intermediate or final product particles within manufacturing can, in turn, produce particles with many different chemical and physical characteristics. This can be illustrated using lactose as an example. Lactose can be crystallized at different temperatures to produce particles of either α-lactose (below a crystallization temperature of 93 °C) or β-lactose (above a crystallization temperature of 93 °C). These powders, although similar in their chemical make-up, have different physical properties, which show different compactability behavior due to the differences in surface forms.[5,6] In some circumstances slight changes in operational temperature or rate of mixing, or changes in concentrations of ingredients within the process, can produce particles which are better suited to one end effect than to others. Characterization of powder surfaces by inverse gas chromatography (GC), coupled with the use of computer models of single-crystal slip planes, has resulted in the thermodynamic discrimination of various powdered surfaces and their modification to improve efficacious drug release. With advances in processing and the measurement of a variety of particle characteristics, this should ultimately lead to a situation in which a chemical process could be manipulated to ''tailor-make'' and design particles for a range of desired functions (M. Ticehurst and I. Grimsey, private communication, 1998).

Throughout this section emphasis is placed on the various and diverse methods and techniques for measuring the sizes of irregularly shaped particles. In general, measurement of irregularly shaped particles can be classified into one of three groups (see points 1–3 in the list that follows). An additional group, although

Encyclopedia of Analytical Chemistry

not size-related, but still essential in the characterization of powdered materials and in the metrology of particle characterization, and which may be of more relevance when solid–liquid particle interfaces are considered is the parameter of surface area and porosity (see point 4).

1. Direct dimensional measurements, as seen with sieving and microscopy. These techniques are explained in more detail in **Sieving in Particle Size Analysis**.
2. Transport measurements. These techniques are explained in more detail in **Sedimentation in Particle Size Analysis**, and **Centrifugation in Particle Size Analysis**.
3. Rapid physical response measurements. These techniques are explained in more detail in
   (a) **Electrozone Sensing in Particle Size Analysis**
   (b) **Light Scattering, Classical: Size and Size Distribution Characterization**
   (c) **Turbidimetry in Particle Size Analysis**
   (d) **Photon Correlation Spectroscopy in Particle Sizing**
   (e) **Field-flow Fractionation in Particle Size Analysis**
   (f) **Ultrasonic Measurements in Particle Size Analysis**
   (g) **Diffraction in Particle Size Analysis**
   (h) **Optical Particle Counting**
4. Surface area and porosity measurements. These techniques are explained in more detail in **Surface Area and Pore Size Distributions**.

The surface area and porosity characteristics of powders may both be calculated from low-temperature adsorption isotherms obtained by gaseous adsorption. The amount of available surface area is generally measured from the lower relative pressure range of the isotherm, while the degree and magnitude of the porosity within powdered or agglomerated material, in terms of macro- and mesopores, is usually derived from the section of the isotherm that has a relative pressure greater than 0.4. For micropores the whole of the isotherm is commonly used for analysis.

In addition to those articles listed above, there are two other articles within this section; one illustrates the use of **Filtration in Particle Size Analysis** and the other addresses the characterization of **Velocimetry in Particle Size Analysis**.

1.1 Historical Background

The emergence of the modern-day discipline of powder technology and thus the measurement of irregularly shaped particles occurred at approximately the same time in North America, continental Europe and the UK during the late 1940s and early 1950s. However, it was believed by Heywood[7] that powder handling and classification of naturally occurring sands and mineral ores can be traced to Egyptian times.[8] The art of sieving in Elizabethan times, together with the settling of mined ores and the technical development of mineral dressings, has been vividly illustrated by Donald.[9] This book traces the formation of one of the first English companies to manufacture an article (in this case copper) as opposed to solely trading abroad. German scientists were brought over to England to extract and smelt the copper ore extracted from mines located in Cumberland and Cornwall. The techniques of metal dressing used to separate, grade and purify the Elizabethan copper had initially been laid down, a few years earlier, by Agricola.[10] A later publication by Ercker[11] showed how ore could be taken from a furnace, stamped (crushed by water-powered mills) into hazelnut- or acorn-sized pieces (2 cm), separated, refurnaced for further purification, stamped again and then graded into a powder which had particles ''liken to the size of meal'' (150–250 μm).

The separation or mineral dressing of ores probably involved the same method of three dry sieving stages followed by three wet sieving stages as given by Agricola and Ercker. The description of the smaller sieves used was ''a wooden tray with a wire bottom never occupied''.

To place into perspective the amount of effort needed to get mined ores into a suitable state for chemical processing, it was found that the cost of mining, stamping and grading the copper was similar to the furnacing, melting and carriage costs of the final product.

One of the first publications dedicated solely to outlining the various mechanico-physical techniques for particle measurement was written by DallaValle.[12]

This was closely followed by a book by Herdan,[13] which concentrated on the conceptualization of the statistics of particles by the combination of both number statistics and physical statistics, as seen in colloidal systems, to give rise to a new discipline called small-particle statistics. Rumpf[14] was concerned with process technology in terms of the transformation of matter by different mechanisms. In chemical process engineering transformation of matter is deemed to occur by chemical reactions, while in thermal process engineering it is regarded as the transformation of thermodynamically defined phases. In both cases the system parameters of pressure, temperature, and composition follow the laws of thermodynamics.[15] Rumpf,[16] however, suggested that there was a third engineering technology that could characterize changes in the state of disperse systems and of mixtures consisting of particulate matter and continuous fluid phases. Rumpf created an area of academic and industrial interest termed mechanical process technology which was a forerunner

of the discipline now known as powder technology. In reality, although a mechanico-physical unit-processing operation may precede and at times terminate a chemical and thermodynamic unit-processing operation, all three technologies are inter-related and essential to the transformation of matter into a desirable end product. Table 1 highlights some of the publications that have advanced the knowledge and technology of particle size analysis and powder characterization.

One of the first symposia on particle size measurements, which was to supply an intellectual interest and stimulus to the subject of powders and solid particles, was held in London in 1947 under the auspices of the Society of Chemical Industries and the Institution of Chemical Engineers. At the opening of this symposium it was stated that, as far as the President of the Institution was aware, no previous attempts had been made to survey or appraise the difficult subject of particle size analysis.

From that symposium, and with the efforts of a few internationally active powder technologists, an expansion in the field of particle size measurement occurred. This was coupled with a greater understanding and comprehension of particle size distributions, particle shape, particle shape distributions and the surface area of powders.

The disciplines of powder characterization and powder technology, which initially emanated from the UK and continental Europe (Table 1), have now become global in their ramifications and acceptability. The forms of particulate matter generated, fabricated, produced and processed have increased enormously, along with the technologies of measurement, since that 1947 symposium. One of the reasons for the dramatic changes in the types of instruments now available, and the use of a wide range of different physical, optical, electromagnetic, and at times electrochemical measurement systems, is due to the advances in computer technology. The amount of data that can be measured, and the speed at which they can be collected, by new and novel measurement systems connected to plant items, has in recent years opened up new frontiers to the powder technologist.[17] Computer-assisted particle measurement instrumentation not only aids the collection of data but also gives the powder technologist the ability to carry out advanced statistical analysis of data gained from real-time measurement systems. The integration of computers to control and automate processing plants, be they chemical, mechanical or powder bulk handling, is extending the original role of off-line laboratory particle measurements to one in which measurements of particle sizes are made on-line and in-line in real time within a chemical processing plant. The ultimate measurement system, which may not be dependent solely on the measurement of particle

size, would be an in situ array of sensors, within a reactor or processing unit. Such a system could detect and characterize one or more particle parameters to control a dynamic particulate process and produce a specifically desired end product. Current research, which is now multidisciplinary as well as multi-authored, is adopting a wider selection of physical criteria than that initially used for off-line laboratory analysis. Through the use of ultrasonics and optical and tomographic sensing techniques, advances have been made to implement in-line particle characterization in the armoury of the particle/powder engineer.[18] Microelectrical resistance tomography has recently been used to find a solution to two problems that were affecting the advancement of particle characterization and the control of particulate processes. A novel in situ method, using resistance tomography, has enabled the measurement of both the size and the shape of a flowing particulate suspension to achieve what is termed an ''electrical texture fingerprint'' of the flowing particles. Use of similar tomographic sensors has also facilitated the access of multivariate data to enable the control and optimization of multiphase particulate and chemical processes.[19,20]

It should, however, be noted that particle size measurement by itself has little or no meaning, unless the reason for the measurement is also specified.

1.2 Selection of an Instrument for Particle Characterization

One of the most important factors that must be borne in mind when approaching any particle size analysis is that, although there are many ingenious, sensitive, reliable and repeatable techniques, no one method can be regarded as perfect. Tabular procedures and flow diagrams have been published[21] that help with the process of choosing an appropriate particle size measurement technique, but a compromise usually has to be made, in terms of cost and time available, to achieve the best particle characteristic or measurement of particle size.

To these ends several techniques are discussed in this encyclopaedia, to illustrate the diversity that exists and which can now be used by the powder technologist.

The choice of a particle size measurement technique is dependent upon the accuracy of the measurement required and the circumstances to which the measurements are to be applied. This rationale was introduced and emphasized by Heywood,[22,23] who is regarded as a founding father of powder technology in the UK, with the words[24]

> However, it must be realised that particle size analysis is not an objective in itself but is a means to an end, the end being the correlation of powder properties with some process of manufacture, usage or preparation.

This point was also made by Herdan,[13] who stated about fifty years ago that:

> Knowledge of the size characteristics of particulate matter is generally of little value in itself; but particle size measurements are often made to control the quality of the final product, because certain sizes may be correlated with certain desirable properties of the product.

This statement was made at a time when Herdan was interested in the statistics of small particles (particles that were generally classified as being either in the sieve or subsieve size range). In terms of physical dimensions, the lower size limit for a woven wire sieve was then customarily recognized as being 75 μm, while subsieve-sized particles had dimensions below this value.

A particle primarily refers to a object that has a physical boundary regardless of its finite size. Because a particle is a discrete portion of matter that is usually regarded as being small in relation to the space in which it is encompassed, the upper size limit of an individual particle is therefore arbitrary. With this definition, planets, rocks, boulders, aggregates, powdered particles, colloids, molecules, and submolecular and atomic entities may all be regarded as being technologically important to a powder technologist.

For practical purposes, however, an arbitrary definition of the size of powder particles has been chosen[25] so that ''a powder shall consist of discrete particles of any material with a maximum dimension of less than 1000 μm (=1 mm)''.

The lower limit these days, because of the introduction of ultracentrifugation, field flow fractionation, ultrasonics, light scattering and X-ray scattering, is commonly taken to be in the submicrometer to colloidal dimensional range (1 nm) (Table 2). With the advent of ''nanotechnology'' this lower limit is being superseded, and instrumentation is being developed to measure particles of this size.[26,27] Because a particle can be defined and described as a discrete entity of matter it is possible to obtain size distributions of populations of solid, liquid or gaseous particles in solid, liquid and gaseous phases by using an appropriate measurement technique.

Although particle size is an important factor in the determination of how a particle will behave, the measurement of that irregularly shaped particle characteristic may be achieved by several different physical techniques, depending on the final objective of the measurement. It is unusual to measure only one particle, thus particle sizing and powder characterization are generally described in terms of a particle size distribution. According to one glossary of powder technological terms,[25] a particle size distribution may be described in terms of the size and frequency of particles in a population, or alternatively as the functional relationship between a quantity of particles

Table 2 Range of particle sizes

Particle size (μm)	Type of particle
10^5 (100 mm)	Roll compacted or pelletized particles and powders, crushed ores
10^4 (10 mm)	Agglomerated or granulated materials, fertilizers, herbicides, fungicides, instant food products
10^3 (1 mm)	Detergents, crystalline sugars
10^2	Powdered materials, chemicals, cement, flour, pharmaceuticals
10^1	Powdered metals, toners, ceramics
10^0	Pigments, magnetic tape particles, air-borne environmental particles
10^{-1}	Organic pigments, micronized pharmaceuticals, contaminants in water and air
10^{-2} (10 nm)	Carbon blacks, fumed silica
10^{-3} (1 nm)	Diesel fuel pollutants, nanotechnology superconductors

and a dimensional measurement of the irregularly shaped particles.

2 SAMPLING OF A REPRESENTATIVE ALIQUOT OF POWDER[28]

Since off-line quality control of a particulate system is retrospective, there is always the possibility of inaccuracies in solid sampling and nonrepresentation of the bulk material.

The purpose of sampling is to obtain a sample (or samples) from a bulk material that is representative of the bulk material in some desired property, which can be particle size, surface area or chemical composition. A perfect sample from a bulk powder is one which contains all the constituents of the bulk powder in exactly the same proportions as the bulk powder. In other words the bulk powder is perfectly mixed and can be regarded as a homogeneously mixed powder.

If a material is believed to be homogeneously distributed in the bulk, then simple random sampling, using a thief sampler or a spoon to obtain samples from anywhere in the powder, is acceptable. Most materials, however, will not be homogeneous, and methods must be devised to achieve a sampling efficiency akin to that theoretically possible from the random variation to be expected under ideal conditions.

There is, however, always a problem with sampling and the taking of an aliquot from a powder, because any attack on a homogeneously mixed powder will cause particle segregation if the powder is free-flowing and noncohesive. There is also the possibility that even if the powder has a degree of cohesiveness there will be particle movement within the powder mass and segregation will again ensue.

Sampling is therefore an error-generating procedure and no sample provides more than an estimate of the truth or reality of a situation.

In the literature on solids mixing, the word ''sample'' has been given a different meaning from that usually intended in textbooks on classical statistics. In the literature on powder technology there is an established practice of using the term ''sample'' to refer to a number of contiguous particles removed from some position in a bulk powder, rather than to an integral unit as presupposed in classical statistics. A representative sample size must thus contain a certain number of particles. This ensures statistically that the sample taken is representative of the whole powder. For example, if 1 g of powder is taken from an industrial powder which has a particle density of $2\,g\,cm^{-3}$ ($2.0 \times 10^{-3}\,kg\,m^{-3}$) and the mean particle size in the powder is assumed to be 100 μm, then the number of particles present in each 1 g aliquot would be in excess of 10^6 particles.

2.1 The Classical Statistical Concept of Sampling

Because there are always many particles in a sample mass taken from a powder, a common approach is to regard powder sampling as being based on number statistics, as seen in many textbooks on classical number statistics. From the viewpoint of classical statistics the sample taken is visualized as an entire single entity and not as a collection of variously sized particles in that powder sample. In classical statistics, however, it is normal to obtain an estimate of some parameter of the single sample, and therefore obtain an interpretation of the deviation of that individual ''sample'' from a series of ''samples'' that all have a simple distribution of values. In addition an arithmetic average or mean, from all the samples, can be evaluated and deviation from that mean observed.

The range of deviation, degree of dispersion or spread of values around a mean can readily be obtained from number statistics, assuming the initial values are normally distributed about a mean value.

In the case of the probability of a number occurring on the throw of a die or dice the variation and distribution of the numbers could be expressed as a binary or Bernoulli distribution. As the number of events increases, for example when considering a million events or the thousands of particles in a gram of powder, a normal (Gaussian or bell shaped) distribution can be assumed. The representation of such Gaussian distributions can then be expressed in terms of

1. standard deviation, or a measure of the extent of a set of numbers dispersed about a mean;
2. variance, or the square of the standard deviation (regarded as a more common alternative measure of dispersion);

3. coefficient of variation, which is the ratio of the standard deviation to the mean;
4. correlation coefficient, which is the ratio of the standard deviations of two variables.

An additional useful estimator that provides an indication of the accuracy of the average estimate is the standard error, which is defined as the standard deviation of the population divided by the square root of the number of items in the sampled unit.

When these classical statistics are applied to sampling it is assumed that all units of the population have an equal chance of being in the sampled unit.

There are several factors that should be considered prior to subdivision or sampling of a powder.

1. Flowability: An assessment of whether the material is free-flowing or cohesive should be made visually or by pouring it through a funnel with an orifice about 1 cm in diameter. This may be affected by other properties listed here.
2. Maximum particle size: The maximum particle size should be assessed. This will not usually exceed 1000 μm, but sample examination and subdivision procedures can be applied for larger particles.
3. Uniformity: The material should be examined to determine whether it contains particles of widely differing chemical nature, density or size, and an assessment made of its likely behavior during sample division.
4. Friability: The tendency of particles to break or erode during handling or under pressure should be assessed.
5. Moisture: The presence of high levels of moisture should be determined. This might be detected by a tendency to coalesce under pressure. A moisture determination may be of value where hydroscopic or efflorescent materials are concerned.
6. Aggregation: The material may show signs of inherent aggregation either on standing or on handling. The presence of aggregates may be detected by a simple microscopic examination. This will also reveal the presence of very small particles which could affect the behavior of the sample.
7. Chemical nature: A knowledge of the chemical nature of the material is necessary to assess its possible reaction with the atmosphere and the working surfaces. The hazards associated with handling the material should be known.

2.2 Sampling Reliability

In the real world, the particle size distribution in a powder does not always show, or even approximate to, a normal or Gaussian model, so conclusions based on classical statistics with a simple mathematical model may not be valid. The objective of sampling is therefore to obtain one or more samples of the bulk material that are representative of that material in some chosen particular. To ensure accuracy, which can be regarded as a measure of the degree to which a value or estimate approaches a ''true'' value and which denotes an absence of bias,the sampling operation must be free of systematic errors.

To obtain precision, which is the measure of the ability of a procedure to yield the same or near identical results from successive treatments of the same sample material, the random errors should be narrowly dispersed about the mean. A well-designed sampling procedure is therefore one in which errors arising from (1) theoretical differences between the operation and the model, and (2) differences between the actual operation and the model, have been minimized.

These errors, which occur in every sampling procedure, can be separated into those that cannot be altered and those that can be minimized. An error that cannot be altered and is inherent in every sampling technique is a fundamental error (FE). This type of error results from the natural variance or inherent random nature of a powder because of the heterogeneity of the particle population. It possesses two important features:

1. it is the only sampling error that cannot be suppressed, as it occurs in ideal sampling;
2. it can be estimated beforehand.

FE can be mathematically expressed as shown in Equation (1).

$$s^2(\mathrm{FE}) = \frac{Cd^3}{m} \tag{1}$$

where $s^2(\mathrm{FE})$ is the variance of $(a_s - a_b)/a_b$ if a_s and a_b are content values of sample and bulk batch respectively; C is the sampling constant, a function of the material's properties, which can be determined from knowledge of the physical characteristics of the particle assembly – particle shape factor, size distribution and mass fraction of the size class under investigation – as well as the statistical variance of the sampling error desirable in the sampling procedure – m is the sample weight; and d is the size of the square mesh sieve required to retain 5% of the particles or a specified percentage of a specified size range of particles.

FE and its variance can be reduced by increasing the sample weight and reducing the value of d. The total model sampling error can be reduced to FE by taking individual particles at random or from part of a homogeneously distributed bulk.

The segregation error (SE) is the expression of the distribution heterogeneity of the bulk to be sampled. It depends on:

1. constitution heterogeneity (as for FE), because the larger the variation in particle size/mass, the greater the segregation;
2. segregation, or the demixing of differently sized particles into zones that then cause the powder to be nonhomogeneous or demixed;
3. weight of the increments (the greater the increment, the larger the group of particles taken each time).

Gy[29] found that the variance of the SE, s^2(SE), can be expressed as equivalent to a segregation factor times a group factor, where the segregation factor is zero for a homogeneous distribution and the group factor is zero for a single particle. To minimize SE, sampling should be made on a bulk material that is as homogeneously distributed as possible, with increments that are as small as possible (although a certain minimum weight is required to limit operational errors).

Another error that can significantly affect the representation of the bulk material by the sample material is the integration error (IE). IE is caused by the type of sampling strategy used to obtain a mass of sample. This error is introduced by the variability in the bulk and the spacing (in distance or in time) between the increments. Thus to reduce IE one should (1) reduce variability by homogenization of the bulk, and (2) sample in the whole space occupied by the batch (or during the whole time), taking increments as close together as possible.

Because IE is related to the type of sampling undertaken, IE can be minimized by using systematic sampling if the error does not vary periodically, or stratified random sampling if some periodicity is present, and by taking the greatest possible number of increments.

Analysis has shown that all theoretical errors, except one, can be reduced to small values by using homogeneous bulk material, by maintaining a constant rate of flow, and by taking a large number of small increments to form the sample. The exception is due to the heterogeneity of the particle population. This error exists even in ideal sampling, and although it cannot be removed, it can be estimated.

The three types of sample strategy in use are

1. random sampling
2. systematic sampling
3. random stratified sampling.

When the bulk material is not homogeneously distributed, random stratified sampling has been recommended to guard against the possibility of cyclic variations in bulk quality. In a continuous delivery operation, sample increments are taken at random times during successive standard time intervals (strata) spanning the whole process. For static bulks the strata could consist of wagonloads, or bags, or a number of bags.

2.3 Selection of Sampling Methods

The objective in the selection of a specific sampling technique prior to particle characterization is to obtain from the laboratory sample a test sample or test portion that represents the laboratory sample as closely as possible. The practice of sampling is based on the premise that there is a theoretical possibility of dividing a sample into smaller samples or portions without the introduction of biased errors. The collection of data from every sample or position in a sample is expected to embrace the mean value of a characteristic of the sample. It must also permit an estimation to be made of any variation of the measured characteristic throughout the sample.

In any homogeneous sample any aliquot or subdivision of the sample will precisely represent the sample as long as the sampling technique does not impart any systematic bias to the subdivision procedure.

When a laboratory sample is known to be a true homogenized bulk, conceptually, any volume selected, without demixing or the separation of particle sizes, will constitute a perfect sample. However, since any particle has a finite volume and real powders have a distribution of sizes, there has to be a minimum volume withdrawn from a homogeneous mixture to obtain both a representative and measurable sample. With such a homogeneously mixed material the technique of scoop sampling could be used to obtain a test sample or a test portion. To ascertain if the laboratory sample is homogeneously mixed with respect to a given characteristic it has to be established that the mean values of all subdivisions are identical in that characteristic.

To verify this homogeneity, several samples or portions must be chosen at random and tested, which in itself is a sampling technique. In reality no material can be deemed to be homogeneously mixed unless sampled.

To assume a homogeneous mix prior to sampling and then to use the method of scoop sampling as a sampling technique can only be justified if, from past experience, the assumption of a homogeneous material is correct and scoop sampling or coning and quartering gives results that are comparable to more sophisticated sampling methods.

When a heterogeneous mix occurs on subdivision, because particles are impeded in their movement throughout the particle assembly, a concentration of certain sizes or characteristics can occur in local positions. The sampling technique must therefore prevent or overcome segregation of these characteristics into local concentrations.

Heterogeneous material is material in which a spot sample, taken from the laboratory sample, will have a significantly different value of the characteristic under investigation from the mean value of the laboratory sample. Unless it is known otherwise, it is advisable to assume that all laboratory samples are heterogeneous and to use a sampling technique that subdivides the laboratory sample into subdivisions that are all representative of the laboratory sample.

Very rarely will the bulk material be homogeneous with regard to the characteristics to be tested. It is a frequent requirement in specifications that a measurement of this inhomogeneity be made. It is then necessary to take several different definitions and masses of samples; the number and size of which will depend on the quantity and particle characteristics of the material.

British Standard (BS) 3406[28] defines the following powder samples:

1. Gross sample: the final sample obtained or prepared from bulk material.
2. Laboratory sample: sample delivered to a laboratory. May be a gross sample.
3. Spot sample: a sample taken from a specified place in the bulk material. May be a gross or laboratory sample.
4. Test sample: a sample prepared from the laboratory sample and from which the test portions are withdrawn.
5. Test portion: that portion withdrawn from the test sample and entirely used in the test or observation.

The minimum size of sample to be taken to represent the bulk material can be derived by assuming that all errors are zero except that due to the spatial distribution of the differently sized particles themselves.

2.4 Attainment of a Test Sample

In general it is not possible to calculate the sample mass required for a given precision because, of all the sampling errors, only the FE can be determined. Assuming that an ideal sampling situation exists and Gaussian distributions predominate, a relation between the variance, sample size, and component proportions will, however, enable the minimum sample size to be determined (Table 3).[30–34]

Table 3 Mass of coarsest particle (particle diameter 1 mm and unit density)

Mass fraction	Minimum sample mass (g)			
	Coefficient of variation			
	0.01	0.05	0.1	0.15
0.01	523.81	20.95	5.24	2.33
0.02	261.90	10.48	2.62	1.16
0.05	104.76	4.19	1.05	0.47
0.08	65.48	2.62	0.65	0.29
0.1	52.38	2.10	0.52	0.23
0.2	26.19	1.05	0.26	0.12

The homogeneity definition requires specification of the size of the test sample or test portion because homogeneity implies that the variability between samples or portions is either negligible or too small to be measured. This should not be taken to imply that homogeneity persists as material is further subdivided. An optimum sample or portion volume must therefore be used which is capable of giving the necessary information about the material it represents.

2.4.1 Free-flowing Powders

With a free-flowing powder there is a greater tendency for segregation to occur than with non-free-flowing, cohesive powders. It is therefore advantageous to sample from a moving stream. This can be accomplished by using a rotary sampler. Various designs exist in this category of sample dividers, but most consist of one or more receivers placed on a turntable that rotates at a specific speed. This type of equipment is thus ideal for free-flowing nonfragile material, but at times can be used for non-free-flowing materials. The abrasion caused by the passage of particles through the sample divider may have an adverse effect on fragile material. A chute riffler can also be used for free-flowing powders.

2.4.2 Non-free-flowing Powders

Although in some cases it may be possible to sample non-free-flowing material with a rotary sample divider or a riffler, in most cases it will be necessary with non-homogeneous and non-free-flowing powders to premix the powder. With such powders it may be advantageous to use a wet sampling technique. The coning process of the coning and quartering technique[28] is to ensure an adequately mixed sample prior to subdivision. The degree of mixing obtained by this technique can in some cases (depending on the chemical and physical nature of the powder), be enhanced by the presence of a small amount of liquid. Continuous handling of the solid is not recommended for fragile particles.

The actual operation of sampling a material stream requires care in design, to ensure that the full cross-section of the stream is sampled on every occasion, that no mechanism is in operation that preferentially accepts or rejects pieces of certain sizes, and that no loss of sample or gain of adventitious material occurs (Figure 1 and Table 4).

Figure 1 Selection of sampling techniques used to obtain a representative sample.

Table 4 Reliability of powder sampling methods

	Coarse/fine sand[a]		Sugar/sand[b]	
	Standard deviation (%)	Coefficient of variation[c] ($\%^2$)	Standard deviation (%)	Coefficient of variation[c] ($\%^2$)
Cone and quartering	6.81	11.4	5.76	9.6
Scoop sampling	5.14	8.6	6.31	6.5
Table sampler	2.09		2.11	
Chute riffler	1.01	1.7	1.10	1.8
Spinning riffler	0.125	0.21	0.27	0.45
Random variation	0.076	0.13	0.093	0.16

[a] Coarse sand, 420–500 μm; fine sand, 150–250 μm, density 2.65 g cm^{-3} for both.
[b] Fine sand as above, sugar, 420–500 μm, density 1.64 g cm^{-3}.
[c] Powder sampling according to BS 3406.[28] Coefficient of variation = standard deviation/mean value.

3 CHARACTERIZATION OF IRREGULARLY SHAPED PARTICLES

In many powder handling, powder production and powder related industries the sizing of particles is traditionally achieved by retrospective physical measurements of the sampled powdered material – off-line laboratory analysis. Off-line sizing of irregularly shaped particles and intermediate primary particles, from either batch or automated production, can only be confidently achieved when a representative sample has been taken from the process. The range of sizes measured off-line by modern instrumentation covers the majority of sizes encountered, from high-throughput, low-value products to low-throughput, high-value ''high tech'' products.

There is no single definition of particle size, as different methods of particle size analysis are based on a wide variety of different physical criteria.

In many textbooks (see Table 1) the particle size of an irregular solid is described in terms of the physical

criterion used to measure the particle's dimensions. Thus, in the past, if the method used to size particles was a mechanical sieving technique, the particle dimension was called the sieve size and had the symbol d_t, while if a sedimentation technique was used, the particle dimension obtained could be calculated and described in several ways, including as a free fall diameter, d_f, a drag diameter, d_d, or a Stokes diameter, d_{St}. ISO (International Standardization Organization) Standard 9276-1[35] now recommends that the symbol x be used for particle size and that a subscript denote the equivalent diameter measured by one of the physical measurement techniques. For example, the electrosensing zone method measures the volume of a particle and this can be identified by the symbol x_v, which is an equivalent volume diameter. Likewise x_s is equivalent surface diameter, x_w is equivalent settling diameter at either high or low Reynolds numbers, and x_n is equivalent mesh diameter.

This, as can be imagined when only the term ''particle size'' was used, has relived some of the ambiguities that could and did lead to confusion when any attempt was made to compare the particle size obtained by one technique with a size obtained by a different physical technique. There is no physical or theoretical justification why any two irregular particle sizes measured by two different techniques should be comparable. A sieve size is not equivalent to a drag or Stokes diameter. This nonequivalence can be advantageous when used to describe the shape of particles, but not when trying to achieve a consensus on the dimensions of an irregularly shaped particle.

Table 5 shows seven arbitrary physical classifications of particle sizing techniques that have been used to measure particle size. Also shown is the descriptive diameter ascribed to the particles measured by that technique. The symbols and nomenclature for particle size and the methods used to obtain a measurement of irregularly shaped particles have recently been re-symbolized. Table 6 shows the new ISO-approved nomenclature. To overcome the confusion that can occur when ''particle size'' is not fully notated, an Expert Group under the auspices of the Bureau Communautaire de Réference (BCR),[36] undertook a certification campaign to measure five powdered reference materials in the size range 0.1–1000 μm and to present the measured particle sizes graphically. It was consensually agreed that the classical treatment of size would be based not solely on physical criteria but on the concept of an equivalent sphere diameter and that the traceable fundamental units of length, mass and time would be used.

For the purpose of these BCR materials the size of the irregular particles was defined as the diameter of a sphere which is equivalent to the particle with respect to either its volume (volume diameter) or to its settling rate in a viscous fluid (Stokes diameter).

A sphere can be measured and defined by one single diameter, a cube by one length dimension and an oblongated body measured by in terms of length, breadth, and thickness. Since an irregularly shaped particle can have various lengths, breadths and thicknesses dependent upon the position of the measurement, it cannot therefore

Table 5 Off-line size-dependent physical criteria for the measurement of irregularly shaped particles

Physical criterion	Diameter measured	Size range applicability (μm)
Direct dimensional measurements		
Image 	Projected area	Optical: 0.8–800 Electron: 0.002–15
Mechanical 	Sieve diameter	Dry: 40–1000 Wet: 1–40
Transport measurements		
Dynamic 	Free fall diameter Drag diameter Stokes diameter	Gravity: 1–100 Centrifugal: 0.05–25
Photo-zone	Projected area Stokes diameter	X-ray: 0.05–100 Centrifugal: 0.05–50
Rapid physical response measurements		
Light scattering 	Surface volume diameter	
Electro-zone 	Volume diameter	
Topography measurements		
Surface 	Surface diameter Surface volume diameter	Permeametry: 0.1–50 (mean) Adsorption: 0.005–50 (mean)

Table 6 International standard nomenclature for particle sizes

Symbol	Name	Definition	Formula
x_v	Volume diameter	Diameter of a sphere having the same volume as the particle	$V = \pi x_v^3/6$
x_s	Surface diameter	Diameter of a sphere having the same surface area as the particle	$S = \pi x_s^2$
x_{sv}	Surface volume diameter	Diameter of a sphere having the same external surface area to volume ratio as the particle	$x_{sv} = x_v^3/x_s^2$
x_d	Drag diameter	Diameter of a sphere having the same resistance to motion as the particle in a similar fluid (for small particles $x_d = x_s$)	$F_d = C_d A \rho_f v^2/2$
x_{St}	Stokes diameter	Diameter of a sphere having the same free-fall velocity as the particle in the laminar region	$F_d = 3\pi x_{St} \eta v\, x_{St}^2 = x_v^3/x_d$
x_a	Projected area diameter	Diameter of a circle having the same area as the projected area of the particle in a stable position	$A = \pi x_a^2/4$

be described or defined by a single or unique dimension and its size may be expressed in terms of the diameter of a circle or a sphere which is equivalent to the particle in some stated particle property (Figure 2). The particle size of an irregularly shaped particle has now been consensually denoted and defined globally[35] as "the diameter of a sphere having the same physical properties: this is known as the equivalent spherical diameter".

There are other definitions for particle size, such as those based on the openings of a sieve or on a statistical diameter such as a Feret's diameter which is measured by image analysis (Figure 3). It should, however, be mandatory that whenever the size of a particle is stated an indication is given of how that particle size was defined and measured. The symbol designated to represent the size of the particle diameter or equivalent spherical diameter in the past has always been "*d*". In many technological publications this is being superseded by the symbol "*x*" because ISO 9276-1[35] has recommended that "*d*" now be replaced by "*x*" to denote an equivalent spherical diameter or a diameter of a sphere. Thus $x_s = (d_s)$ = equivalent surface area diameter and

Figure 2 Equivalent particle diameters (after Heywood[23,94]).

Figure 3 Alternative definitions of particle size by image analysis.

$x_v = (d_v)$ = equivalent volume area diameter, although this change in nomenclature is not mandatory.

3.1 Graphical Representation

Most modern instruments present the measurement results in graphical form, but at times it is necessary to express these results quantitatively so that only a single representative measurement is used and introduced into some particle system correlations and particulate models. Some of the simplest correlations reduce a particle size distribution to a single parameter. The statistical parameter calculated can be a mean size, a median size, or a modal size. These single averaged parameters can thus convey, by a single number, the order of the particle size involved within a distribution, but such a single parameter gives no indication of the spread of the distribution. The mean size is the average of the distribution. The median size, where half of the particles

are smaller and half are larger than the median size, is the midpoint of the distribution and is often denoted by the symbol x_{50}. Finally, the modal size is the size that occurs most frequently within the distribution and is thus the location of the maximum quantity within the distribution. Powders can, however, have more than one modal value and particle size distributions can be mono-, bi-, tri- or even multi-modal.

As powders are assemblies of particles, a powder can be characterized in terms of its distribution of particle sizes by a statistical parameter that is chosen to typify both the type of distribution and the average particle size within that distribution.

The distribution is usually determined either as a number distribution or as a distribution by weight, and the information may be displayed graphically either as a histogram or as a continuous distribution curve. ISO 9276-1[35] recommends that measurement of a distribution be graphically displayed as either a discrete density distribution, q, or a cumulative distribution, Q (Figure 4). A cumulative distribution curve is used most often because the curves can be more easily interpolated and normalized. The word ''density'' denotes a statistical parameter akin to the frequency of an event in number statistics and should not be confused with the physical property of mass per unit volume.

Since a powder consists of many particles which have a range of sizes it is possible to mathematically describe that range of sizes using Equation (2)

$$Q_r(x) = \int_{x_{\min}}^{x} q_r(x)\,\mathrm{d}x \tag{2}$$

where x represents a particle size, $Q_r(x)$ is the cumulative distribution, and $q_r(x)\,\mathrm{d}x$ the fraction of particles in the size range $(x - \mathrm{d}x)/2$ and $(x + \mathrm{d}x)/2$. The subscript r describes the type of distribution as well as the type of diameter measured. Thus when $r = 2$ the distribution is by area and the diameter measured is equivalent to a projected surface (x_s), while when $r = 3$ the diameter is a volume diameter (x_v), as determined by an electrosensing technique (Figure 5). It is, however, customary to normalize particle size distribution so that the total area of the distribution is unity, by imposing the condition shown in Equation (3)

$$Q_r(x) = \int_{x_{\min}}^{x_{\max}} q_r(x)\,\mathrm{d}x = 1 \tag{3}$$

where $x_{\max}$ and $x_{\min}$ are the largest and smallest particle sizes in the distribution.

The fraction of particles in the term $q_r(x)\,\mathrm{d}x$ can be expressed in several ways. If the particle size measurement technique involves sieving then the graphical representation would be by weight (for constant particle density (mass/volume) the distribution becomes one

Figure 4 Graphical representation of particle sizes.[35] (a) Cumulative and density distributions; (b) cumulative and density logarithmic distributions. $\bar{q}_0, \bar{q}_1, \bar{q}_2, \bar{q}_3$, density distribution by number, length, surface or projected area, volume or weight; Q_0, Q_1, Q_2, Q_3, cumulative distribution by number, length, surface or projected area, volume or weight; $\bar{q}_0, \bar{q}_1, \bar{q}_2, \bar{q}_3$, density distribution by number, length, surface or projected area, volume or weight with logarithmic abscissa. (Reproduced with permission from BSI and ISO monographs.)

Figure 5 Statistically defined particle size distributions. Number, $r = 0$, length, $r = 1$, area, $r = 2$; volume or mass, $r = 3$.

Table 7 Statistically defined particle size distributions[35]

Type of distribution	Measurement of distribution of particle size, x	
	Density distribution	Cumulative distribution
General symbol, $r = r$	$q_r(x)$	$Q_r(x)$
Number, $r = 0$	$q_0(x)$	$Q_0(x)$
Length, $r = 1$	$q_1(x)$	$Q_1(x)$
Area, $r = 2$	$q_2(x)$	$Q_2(x)$
Volume or mass, $r = 3$	$q_3(x)$	$Q_3(x)$

which can be equated to a volume distribution, thus $r = 3$). If the particle size is measured by image analysis then the representation would be by number ($r = 0$) or area ($r = 2$). With a light-scattering particle size measurement technique an area distribution would be appropriate.

Table 7 shows the types of particle distribution that can be statistically defined (number, length, area and volume or mass) together with the terminology used to define density and cumulative distributions.

3.2 Particle Averages and Particle Size Distributions

To unambiguously describe the average size of the particles in an assembly or distribution of particles or powder, two statistical criteria are necessary. These criteria can be denoted by two subscripts attached to the symbol (x) for particle size. One subscript is related to the type of statistical distribution (r) and the other is related to the method used to calculate the average size of the particles (k) within the distribution.

The general description of an average particle size within a powder is thus dependent upon both the type of size distributions and the method of calculation from moments of the particle size mean. The moment of a distribution can be represented by the letter M qualified by two subscripts, where $M_{k,r}$ is the complete kth moment of a $q_r(x)$ density distribution,[37] as shown in Equation (4).

$$M_{k,r} = \int_{x_{\min}}^{x_{\max}} x_r q_r(x)\,\mathrm{d}x \qquad (4)$$

The first subscript denotes the power of the moment and the second denotes the power of the distribution function.[38,39]

This elegant nomenclature is not often used in practice. It is, however, extremely useful as it illustrates that a distribution can have an infinite number of ''average'' sizes.

In particle size analysis particulate matter is often characterized and based on a representative sample of the powder population, and the particle size is then related to some other important physical property such as strength, flowability or solubility. A more meaningful correlation may, at times, be obtained if a specific average particle size (from the range of averages that could be obtained using moments of a distribution) is derived or calculated from the measured distribution of particle sizes, and this specific average size can then be related to a process variable. Equations for the calculation of average particle sizes or average particle diameters from a given particle size distribution are defined in ISO 9276-2[39] to give a unique definition of average size, derived from the moments of a size distribution. As more than one moment can be calculated from a distribution, a range of averages can therefore be calculated from a measured particle size distribution. However, not all of these theoretically possible averages have a practical use in powder technology.

From the moments in a distribution, the average particle diameter can be expressed as $x_{k,r}$, where r is type or quantity of the distribution (Table 7) and k is the power of the moment of size x or the kth moment of the density distribution. Several combinations of the values of r (0 to 3) and of k (3 to -3) can therefore be obtained, which shows the wealth of averages that can be calculated. Table 8 illustrates the method of calculation of averages and weighted averages and shows some of the more common averages used in powder technology industries.

3.3 Statistical Analytical Distribution Functions

An alternative approach to describing a particle size distribution in terms of moment averages is to fit the distribution curve into an analytical function. Some of the most commonly used functions are the Gaudin–Schuman distribution, the log-normal distribution, and the Rosin–Rammler distributions. In each case

Table 8 Calculation of averages and weighted averages

Average particle diameter[a]	$x_{k,r}$
Arithmetic average particle diameter[b]	$x_{k,0}$
Weighted average particle diameter[c]	$x_{1,r}$

[a] Depending upon the chosen number of the subscript ($k = -3, -2, -1, 0, 1, 2, 3$ and $r = 0, 1, 2, 3$) different average particle diameters can exist. The arithmetic mean particle diameters are, however, always based on a number density distribution, so $r = 0$.

[b] Recommended arithmetic average particle diameters are $x_{1,0}$ for arithmetic average length, $x_{2,0}$ for arithmetic average surface area, $x_{3,0}$ for arithmetic average volume.

[c] k is the power of the dimension used to characterize or measure the particle size, x, which can be a volume (x^3), a surface area (x^2), a length (x^1), a number (x^0), a reciprocal length (x^{-1}), a reciprocal surface (x^{-2}) or a reciprocal volume (x^{-3}). The recommended weighted average particle diameters are $x_{1,0}$ from number density, $x_{1,1}$ from length density, $x_{1,2}$ from surface density and Sauter diameter, $x_{1,3}$ from volume density.

the equation contains two constants, one of which is a characteristic of the particle size while the other is dependent upon the width of the size distribution. Although these functions are sometimes convenient to use, they should not be extrapolated outside the range of the actual measurements.

3.3.1 Gaudin–Schuman Distribution

The Gaudin–Schuman distribution is shown in Equation (5).

$$Q_r(x) = Q_3(x) = \left(\frac{x}{x_{\max}}\right)^m \tag{5}$$

This expression is included because it is an example of a simple power law. Plotted on a logarithmic scale the distribution is a straight line. The characteristic size is that of the largest particle, $x_{\max}$. The width of the distribution or decrease of scatter is signified by the slope, m. The wider the distribution, the smaller the slope.

3.3.2 Rosin–Rammler–Sperling–Bennet Distribution

The Rosin–Rammler–Sperling–Bennet distribution is shown in Equation (6).

$$R(x) = 1 - Q_r(x) = 1 - Q_3(x) = \exp\left(-\left(\frac{x}{x'}\right)^n\right) \tag{6}$$

This distribution is based on an exponential function and thus tends to be applicable in a process where many random events occur consecutively. It is often used to describe the products of a comminution process. The function can be plotted as a straight line on a natural log of a natural log (ln ln) versus natural log (ln) scale. By taking natural logs twice, Equation (7) is obtained

$$\ln\ln\left(\frac{1}{R}\right) = n\ln x - n\ln x' + \ln\ln \mathrm{e} \tag{7}$$

where $\ln \mathrm{e} = 1$ and $\ln\ln \mathrm{e} = 0$.

The characteristic size x' is the size of x corresponding to a cumulative percentage $Q_3(x)$ equal to 63.2% undersize or an oversize of 36.8%. The width of the distribution or decrease of scatter is signified by the slope, n.

3.3.3 Log-normal Distribution (Gaussian/Laplace/De Moivre)

The normal distribution can be described by Equation (8).

$$q(z) = \left(\frac{1}{\sqrt{2\pi}}\right) \exp\left(\frac{-z^2}{2}\right) \tag{8}$$

This is the Gaussian normal distribution, which describes a completely random distribution of sizes around some mean. In a distribution which has a linear abscissa for particle size then z becomes equal to $(x - x_{50}, r)/2$ and for a logarithmic abscissa for log sizes z becomes equal to $\ln(x/x_{50}, r)$. The Gaussian curve can be useful for some narrow, naturally occurring distributions. Usually, the size distributions of powders are too wide for this function, and the log-normal distribution must be used. If this distribution is applicable a plot of probability versus ln size will yield a straight line. The width of the distribution or decrease of scatter can be signified by the slope, s. If the distribution has an arithmetic or normal distribution then $s = (x_{84} - x_{50}) = (x_{50} - x_{16})$, where x_{84}, x_{50} and x_{16} are the values of size at which $Q_r(x)$ is 84%, 50% and 16%, respectively.

With a log-normal distribution $s = \ln(x_{84}/x_{50}) = \ln(x_{50}/x_{16})$.

To obtain an evenly spaced graphical representation of a wide distribution of sizes, which will ensure the "noncrowding" of sizes together, the size axis can be changed from an arithmetic scale to a logarithmic scale. The degree of resolution of size, or space between points, is shown in Table 9. With the arithmetic scale the distance between the points decreases with an increase in particle

Table 9 Degree of resolution for arithmetic and geometric progressions

Arithmetic progression									
Size	1	2	3	4	5	6	7	8	9
Class interval	–	1	1	1	1	1	1	1	1
Mean class size		1.5	2.5	3.5	4.5	5.5	6.5	7.5	8.5
Degree of resolution	–	0.66	0.40	0.28	0.22	0.18	0.15	0.13	0.12
Geometric progression									
Size	1	$\sqrt{2}$	2	$2\sqrt{2}$	4	$4\sqrt{2}$	8	$8\sqrt{2}$	16
Class interval	–	$\sqrt{2}-1$	$2-\sqrt{2}$	–	–	–	$8-4\sqrt{2}$	$8\sqrt{2}-8$	$16-8\sqrt{2}$
Mean class size		$(\sqrt{2}\times 1)^{1/2}$	$(2\times\sqrt{2})^{1/2}$				$(8\times 4\sqrt{2})^{1/2}$	$(8\sqrt{2}\times 8)^{1/2}$	$(16\times 8\sqrt{2})^{1/2}$
Degree of resolution	–	0.347	0.348	–	–	–	0.348	0.348	0.348

size, while with a logarithmic scale the distance between points remains uniform.

In current particle and powder processing the required particle mixtures may be elaborate and thus far more complex than can be described by a two-parameter model. Modern computing techniques do, however, enable the easy solution of numerical equations and the computer can accept the distribution function as a series of numbers which can then be readily visualized graphically on a computer screen.

4 THE METROLOGY OF PARTICLE CHARACTERIZATION

In considering particle-measuring techniques, the first major distinction that should be made is between direct and indirect methods of measurement. If the particles can be directly observed by an optical microscope or an electron microscope then an indefinite amount of information can be obtained from the image of the particles. Frequently, there is a limitation on the number of particles that can be analyzed in a reasonable time, so image analysis techniques are usually used for more sophisticated experimental and research analyses. In principle, any physico-chemical phenomenon which is dependent upon particle size can be used to measure a particle dimension. In practice it is more convenient if the relationship between the phenomenal mechanism and the particle size is known. Currently there is a wide range of commercially available equipment, but it is based on relatively few physical principles. Nanotechnology has been used in the production of electrospray-dried biomolecules[40] and thermoelectrically and electronically configured nanofilms and nanocomposites.[41] The advent of this technique, together with concerns over the emission of nanosized particles and microsized particulate masses from low-emission diesel engines,[42] and the introduction of new legislation on air quality,[43,44] has meant that other size-dependent physical properties may have to be used for particle size characterization and incorporated into new and novel measurement systems.[45] Air pollution regulations do not apply only to the automotive industries since National Ambient Air Quality Standards are mandatory for most powder producers and users.[46]

New physical principles, such as those used in differential mobility analysis, small angle X-ray scattering and ultrafine condensation nucleus counting, may have to be considered for the future measurement of nanoparticles as well as the modification of accepted metrology to discriminate between, measured and monitored micrometer and nanometer particle sizes.

The methods that are commonly used these days for characterizing industrial powders, both off-line and in some cases on-line, are:

- sieving
- sedimentation
- electrical sensing zone techniques
- light scattering
- ultrasonic attenuation.

The first three are established off-line techniques that have been thoroughly tested and developed, and from which reproducible and replicatable results can be obtained. They are, however, less amenable to automation and on-line application. The last two techniques are at present generally off-line measurement techniques but are amenable to further technological modifications for use in automated powder processing plants.

4.1 Off-line Metrology

Off-line metrology, as seen in modern particle size instrumentation (Table 5), can be categorized as shown in the following sections.

4.1.1 Direct Dimensional Measurements

These measurements are typified by the microscopy and sieving techniques that are generally applied to particulate systems in the 10–25 000 μm size range (although the maximum particle size of a powder is generally accepted to be below 1000 μm). The lower size limit can be extended to the 1 μm level for both techniques.[47] Particles undergoing size analysis by sieving have to be robust to withstand the sieve action, which can cause attrition when a ''dry'' sieving technique is used. For fragile particles there is a ''wet'' technique, in which water or organic solvents are used to support delicate materials, and when either wire or electroformed sieves are used.[48–50] The particles must be insoluble in the suspending fluid.

4.1.2 Transport Measurements

Metrology based on the transport phenomena of particles, as seen with Stokesian sedimentation and elutriation, covers a particle size range from 10^{-3} to 10^{-6} m (1000 μm to 1 μm) when the force causing particle settling is gravity. The sizes measured by centrifugal separation are smaller and generally in the 0.05–25 μm range (Table 5). Recently it has been argued that the lower particle size limits for gravitational sedimentation can theoretically be specified in terms of height and time of fall, rather than relying on the vague statement that the Reynolds number should be less than 0.25. The lower particle size limits for gravity

sedimentation were found to be inversely proportional to the cube root of the measurement height and inversely proportional to the fifth root of the measurement time.[51] Convection currents will, however, always exist within a particulate gravitational suspension system with particle sizes of less than 1–2 μm. Thus a protracted measurement time, to achieve a supposed measurement of particles below 1 μm, tends to be suspect because of mass flow and possible temperature variations which cannot, with any degree of certainty, be measured. It is therefore essential that there is an increase in the degree of temperature control when the sizes of particles being analyzed by gravity sedimentation decrease below 50 μm.

4.1.3 Rapid Physical Response Measurements

Rapid response particle size analysis can be achieved with electrozone sensing, Fraunhofer diffraction and nephelogenic (light scattering) techniques. In diffraction and light scattering instruments the intensity of light scattered by the particles, usually in suspension, is recorded as a function of the scattering angle. The light scattering models used to determine particle size from rapid response instruments depend on Fraunhofer diffraction, Mie theory or ray optics.[52,55] The size range measured with this group of instruments, unlike the unlimited size range of the direct measurement group, tends to be between 10^{-3} m (1000 μm) and 10^{-7} m (0.1 μm). Colour absorbance coupled with radiation absorbency may cause some inaccuracies in photozone sensing. With light scattering instrumentation, which is dependent upon the computational models that deconvolute the measured scattered light intensities falling onto photodetectors, it is always assumed that the light scattered emanates from spherical particles. Thus either an under- or an overestimation of the finer particle sizes in a distribution may occur because of either the computer model or the insertion of incorrect particle and suspending fluid physical data into the computer program. The anomalies seen in laser light scattering instruments may at times be due to instrument misalignments, but the main source of error is due to incorrect choice and application of the computational model used for different types of particles, refractive indices or particle size distributions. The electrozone sensing technique can give size measurement distortions with highly conductive or very porous materials, because of incorrect volume displacement.

When the laser diffraction technique was first introduced, the scattering angles were less than 14°, but now instrumental technology has advanced and the ISO monographs (Table 10) have divided laser light scattering techniques into two or more categories. Low-angle laser light scattering (LALLS) instruments limit the minimum particle size that can be measured by this technique to 1 μm. The laser technique has now been broadened to capture light scattered over a much wider angular range. Other improvements include the placement of light detectors at various angles to the incident beam and the use of lasers with different wavelengths of light and polarization. Many recent instruments now have angles up to and at time greater than 150°. With the application of Mie theory[54] as well as the approximate theories of Fraunhofer and anomalous diffraction,[52] particle sizes down to the sub-micrometer range or less (<0.1 μm) can readily be analyzed with converging beams and more than one focusing lens. Since all the theories used are based on the scattering of light from spherical bodies, irregularly shaped particles in the nanometer size range can theoretically be measured. The measured/computed size for nonspherical particles is the equivalent sphere size, which is an equivalent cross-section generally termed the Sauter diameter (or in ISO terminology the $x_{1,2}$ (average length-surface)) or the average volume-surface diameter.

4.1.4 Topography, Surface Area and Porosity

In many powder technology industries, such as pharmaceuticals, foods, ceramics and cosmetics, information on a range of different particle and powder characteristics which can be used for discriminatory tests on resources – to measure the purity of solid materials and as aids to facilitate product improvement and development – as opposed to the particle and bulk characteristics

of powders to facilitate industrial production, has always been of paramount importance.

One of the alternatives to measuring particle size and shape, and one which is becoming of more and more importance mainly because of the ease with which it can now be measured, is measuring the surface area of a powdered solid.

The ease of agglomeration and compaction, together with many other powder technological processes, can vary greatly for materials that have chemically identical structures but possess differing physical natures. Expressing the physical nature of the materials in terms of the energy, enthalpy, solubility or dissolution potential per unit surface area has thus enabled optimization in the choice of preferred raw resources. Whenever a solid is in contact with a fluid the interface between these two phases is dependent upon the surface area available to interact with the surrounding fluid, be it gaseous or liquid.

4.1.4.1 Surface Area of Powdered Material Measurement of size, shape and size distribution is generally accepted as a means of characterizing simple end-user products, but with more complex particles, surface-modified granulates and ''high tech'' designer multifunctional powder systems, the parameter of surface area together with inter- and intraparticulate space within aggregated, agglomerated or compacted powders can give a more meaningful explanation of particle–particle behavior. The need to control particulate structures and to modify the surface of the resultant product is thus an emerging commercial demand. The morphology of a particulate surface can either be described as rugged or tortuous as opposed to a smooth surface. Fractal geometry, from image analysis, can be used to describe not only the particles' shape but also the texture or roughness of the agglomerated surface. Penetration into all the cracks and crannies which are generally present on the surface of a rugged particle is best accomplished by the adsorption of a fluid onto the surface of a solid.

Because of the wide use of powdered material in various fields of engineering and technology there is no unique method for analysis or characterization of the topography (surface) or the internal structure (pore/void distribution) in complex porous matrixes. The surface areas of size-enlarged particles or powders are generally determined from the monolayer or multilayer adsorption region of a low-temperature nitrogen adsorption isotherm using the Brunauer–Emmett–Teller (BET) equation.[55] The multilayer and capillary condensation region of the low-temperature nitrogen isotherm can also be used to evaluate the size and shape of pores within particles or the voids between particles. The maximum relative pressure achievable with low-temperature adsorption equipment usually limits the pore/void measured to a size not greater than 500 nm.[56–58]

The nitrogen BET method[55,59,60] is one accepted technique for the measurement of surface areas. Another, mainly used for low-surface-area powders ($<1.0\,m^2g^{-1}$), is krypton adsorption. The protocol of surface area measurement, together with the comparison of measured surface area values of powders against standards that have been approved by the powder technology community, is therefore a necessity in global validation of powdered materials. One of the most comprehensive descriptions for the determination of surface area and porosity by physisorption has been published by the International Union of Pure and Applied Chemistry (IUPAC).[61,67]

The degree of humidity is another important factor in the preparation and assessment of the mechanical properties of particles, powders, cakes and compacts. Most problems encountered in the formation and subsequent behavior of particulate material can be related to the influence of either a liquid or gaseous phase on the solid surface interface. Elbirli et al.[62] have shown that the degree of humidity controls the extent of capillary condensation of water between points of contact between particles.

The shear strength of packed beds of rounded, spherical type particles decreases with an increase in humidity. However, with irregularly shaped, angular particles with sharp contact points an increase in the adhesive force, and thus the shear strength of a powdered bed occurs with an increase in humidity. This contradiction is dependent upon the presence of liquid rings or the onset of the funicular state between particles. These phenomena are in turn dependent upon the surface area and surface irregularities of particles. Since the presence of moisture is generally influential in either the agglomeration or disintegration and dissolution of powdered materials, investigation into the effect of moisture, by the determination of water adsorption isotherms, is one of the more important characterization techniques used to measure the specifications and properties of compressed and uncompressed aggregates, granules and agglomerates of fine particles. The specific surface area of particulate and granulate material can be calculated from the BET equation at low temperature (77 K), but at room temperature it has been found,[63] because of the increase in the range of linearity, that it is preferable to use the Huttig equation[64] rather than the BET equation for surface area measurements by water adsorption.

Information obtained from either nitrogen or water physisorption measurements is at times limited to the surface topographical features of the solid, but recently analysis and interpretation of nitrogen and water adsorption–desorption isotherms has been extended using the

generalized Dubinin–Astakov equation[65] to determine the energetic heterogeneity of surfaces.

When the interparticulate sizes within compacts are greater than those readily measurable by low-temperature adsorption and application of the Kelvin equation (i.e. greater than 500 nm), the technique of mercury intrusion porosimetry (section 4.1.4.3) can evaluate intraparticle and interparticle space in the approximate size range from 3.5 nm to 1.0 μm.[58,66]

4.1.4.2 Porosity in Particles The techniques available for the physico-chemical characterization and measurement of either intraparticular and interparticular space are dependent upon the magnitude of the space dimensions to be measured. The material matrix within an agglomerated or compacted mass of powder may have pores or voids that are generally in the 1.0 nm to 0.1 mm size range. These pore/void spaces can be sized by the physical adsorption of various vapors or gases at low (nitrogen, krypton and carbon dioxide) and ambient (water, butane or organic vapors) temperatures. Since the techniques chosen for the characterization of porous materials are, to some extent, dependent upon the dimensions of the space to be measured and the mechanisms of pore space filling, it is expedient to classify pore space or porosity in terms of the dimensions of the space, with the caveat that the size limits are arbitrary and can be influenced by the interactions of the solid and fluid used in the measurement technique. Pores exceeding 50 nm in width are generally termed macropores, while pores with a width not exceeding 2 nm are micropores. Pores of intermediate sizes are termed mesopores.[67]

Mesopore Space. Although there is no single current theory of adsorption capable of providing a comprehensive mathematical description of physisorption isotherms over the entire range of relative pressures, it is possible to determine from an isotherm not only the surface area of a particulate solid, but also information on the texture, pore spaces or topography of solid materials from the multilayer and the capillary condensation regions of the isotherm. The demarcation between external and internal surface is dependent, however, on the accessibility, size and shape of the adsorbate molecules, as well as the pore space distribution in the solid. In the case of a solid which has mesoporosity, the adsorption isotherm tends to remain nearly horizontal as the relative pressure range approaches unity. The total pore volume can be evaluated in such isotherms – usually classified as type I or IV BDDT (Brunauer–Deming–Deming–Teller)[68] isotherms – from the Gurvitsch Rule.[69] When macropores are present the adsorption isotherm tends to rise rapidly near the relative pressure value of unity and reliable total pore volume measurements can only occur with carefully controlled experimental procedures. This type of isotherm is usually classified as a type II BDDT isotherm.

Micropore Space. When the dimensions of the adsorbate are similar in magnitude to the capillary dimensions within solids, the filling of these spaces (micropores) at low temperature results in a type I BDDT isotherm. Type I isotherms in most cases do not show hysteresis with microporous material, although narrow hysteresis has been found with some adsorbate–adsorbent systems.

Lippens et al.[70] showed that the specific surface size and shape of micropores can be obtained from a plot of experimental adsorbed volumes at specific relative pressure versus the statistical thickness at the same relative pressure of an adsorbed layer on a nonporous solid. Unhindered formation of multilayers on nonporous surfaces produces a linear relationship, passing through the origin between the volume adsorbed and the thickness of the multilayer adsorbed on the nonporous solid, a V_{a-t} curve. The slope of this line is a measure of the surface area of the porous or nonporous material. At higher relative pressures, and thus larger t values and pore space dimensions, deviations from linearity can occur. At certain relative pressures more adsorbate can be adsorbed into specifically shaped and sized pores than onto a corresponding nonporous solid. A decrease in adsorption will cause a decrease in the slope of the V_{a-t} relationship – the curve becoming convex to the x axis – and this is indicative of microporosity. An increase in the slope of the V_{a-t} equation occurs when the size of the pore space is larger or slit-shaped, and is indicative of mesoporosity.[71] Differentiation of the V_{a-t} curve or Sing's α_s plot,[72,73] at known relative pressures and thus pore radii, is the basis of the micropore analysis method of Brunauer et al.[74,75] It is essential, however, in the determination of micropore space distributions, that a nonporous reference solid t-curve be chosen which has an adsorption coefficient value similar to that of the unknown structure. Provided that the micropore size distribution is not too broad then excellent agreement between derived values of micropore volume and pore width can be obtained with Sing's ''alpha s'' (α_s) plot and the Dubin–Radushkevich equation.[76]

4.1.4.3 Mercury Intrusion Porosimetry Determination of the pore space distribution by mercury porosimetry has, because of the relative simplicity, versatility and speed of the technique, been used for many quality control characterizations in preference to other techniques. The range of porosimeters available and discussions on the accuracy and reliability of the mercury intrusion method have been covered by Orr[77] and van Brakel et al.[78] The principle of mercury pore space distribution is based on the fact that mercury does not wet most materials

(the contact angle is greater than 90°). One of the difficulties in interpretation of mercury porosimetry results is the inability to distinguish between penetration into inter- or intraparticle space. With nonporous material only interparticle space exists, but many compressed and uncompressed particles contain intraparticle space. Critical examination of porosimetry curves may, at times, show two sharply defined regions, one at relatively low pressures and the other at higher pressures. It is thus beneficial to measure an overall pore–void size distribution over the 1 nm to ca. 50 μm range using both the adsorption and mercury penetration techniques. This then aids the recognition and discrimination of the interparticle and intraparticle spaces, especially with microporous particles.

4.2 In-line and In Situ Particle Characterization

Orr[79] and later Leschonski[80] described the start of a new era involving rapid-response particle–process-control sizing instruments, while Scarlett[81] highlighted the statement that Heywood[24] had made many years before: ''a size analysis procedure which can form part of a fully automated production unit will be needed to feed back information to the process''.

On-line monitoring and process control does not, however, remove the problem of obtaining a representative powder sample. It only changes the essential sampling operation required to obtain a particle-process parameter from a manual laboratory collection of particles to a possibly automated particle collection process. These on-line sample collection processes, followed by size or particle characterization techniques, may have computer control, collect many more powder samples and possibly have more rapid-response times, but on-line particle characterization still does not overcome the problem of collecting, removing and transporting the particulate sample to the particle characterization instrument.

As time, effort and money can be wasted by analysis of a nonrepresentative sample, the emphasis for size measurement/characterization, with the advent of computerized information technology, has shifted from off-line batch techniques to on-line and in-line analysis. Ultimately the desired goal for many process and product engineers is in situ particle characterization and control. On-line measurements nowadays are largely devoted to modification and adaption of off-line methods.[79,83,84]

Even if the on-line analysis has a rapid response of only a few seconds or parts of a second this will eventually be superseded by in-line and/or in situ particle size and size distribution measurements.

In-line and in situ methods of characterizing particulate systems attract the attention of industry because:

1. The physical characteristics of the particles in a chemical process influence both the dynamics of the process and the final product specification.
2. In a dynamic continuous chemical process there should be a continuous dynamic measurement that can control the particle characteristics of the powdered material in terms of particle size, particle size distribution, shape, bulk density and other particle or powder characteristics.
3. Characterization of the mechanics and dynamics of the chemical process itself is also essential, initially to understand the process, then to control, improve and optimize the plant in terms of safety and cost effectiveness, and finally to tailor-design the final product from the chemical process.

Laser-based particle characterization instruments may be ideally positioned to achieve in-line or in situ particle size analysis because of the manner in which particles are detected and the ease with which computational manipulation of the collected information, needed to record a desired particle size or process parameters,[85] can be accomplished.

5 SHAPE CHARACTERIZATION OF IRREGULAR PARTICLES

The need nowadays is not only for the measurement of size and size distributions, but also for the measurement of shape and shape distributions. Although Rose[86] stated in 1961 that: ''perhaps one of the most abortive searches yet made is for a means of defining the shape of a particle'', many workers are now currently appraising past work on shape factors. Shape measurement, initially of academic interest only, began to find credibility when shape characteristics were incorporated into industrial and commercial powder and granulate specifications.

The complexity of shape analysis by analytical methods other than Mandelbrot[87,88] fractal analysis emphasizes the need to describe shape by more than one technique and parameter.

Most instruments for shape analysis compare the profile of an irregularly shaped geometric particle with that of a known geometric shape such as a sphere, cube or rectangle. The shape of the irregular particle is then described in terms of length and width or simply a ratio devised from computer image analysis. The main approaches to the development of techniques and instruments to characterize and measure the shape of irregularly shaped particles can be illustrated in several ways, as shown in Figure 6.[89,90]

Figure 6 Various techniques for characterizing the shape of irregular particles.

5.1 Direct Measurement of Single Particle Shape

5.1.1 Dimensionless Geometric Shape Factors

Particle shape is a fundamental characteristic of a particle, in a manner similar to particle size. In BS 2955[25] various types of particle shape were described in words, and numerous general shapes have subsequently been defined (Table 11). These verbal descriptions are, however, inadequate for incorporation into equations and calculations to ascertain the effect of particle shape on various particle systems, particle properties or the design of bulk powder handling equipment. One of the first attempts to standardize particle shape measurement for individual particles was by measuring the length or

Table 11 Definitions of particle shape

Shape	Definition
Acicular	Needle-shaped
Angular	Sharp-edged or having a roughly polyhedral shape
Crystalline	Freely developed in a fluid medium of geometric shape
Dendritic	Having a branched crystalline shape
Fibrous	Regular or irregular thread-like
Flaky	Plate-like
Granular	Having an approximately equidimensional irregular shape
Irregular	Lacking any symmetry
Modular	Having rounded, irregular shape
Spherical	Global shape

diameter and the breadth or width of a particle and then, from the protocol outlined in BS 512 (1966), assigning different and arbitrary ratios of particle breadth to length, B/L, and particle thickness to breadth, T/B, to various three-dimensional particle shapes. Regular geometric shapes, such as disks, rods, blades and equidimensional particles, could then be assigned a numerical value relating to the shape of the body or particle rather than a literal description.

Herdan[13] had stated, before the publication of BS 512 (1966), that any ''shape factor'' should have a three-fold function:

1. It should be a factor of proportionality between the particle size determined by different methods of particle characterization, so that, for example, the particle size determined by microscopic techniques could be compared with that determined by sedimentation.
2. Shape factors should be conversion factors for expressing the results of different particle measurement techniques as an ''equivalent sphere'' parameter.
3. Shape factors should transform the second and third powers of a measured particle diameter into the parameters of particle surface area or particle volume.

The volume of a particle can thus be expressed as the volume coefficient (volume shape factor) multiplied by the cube of some characteristic dimension. Similarly, the surface area of a particle can be expressed as the surface coefficient (surface shape factor) multiplied by the square of some characteristic particle dimension.

Algebraically these definitions can be written as shown in Equations (9) and (10)

$$V = \alpha_v x^3 \tag{9}$$

$$S = \alpha_s x^2 \tag{10}$$

where x is the size characteristic of the particle and α is a shape factor. Using a microscope count method, the size characteristic as a one-dimensional quantity can be either a Feret's diameter or a projected area diameter, x_a. As the volume and surface area values for a given particle are fixed, the numerical values of the coefficients of shape α_v and α_s are thus dependent on the chosen size characteristic. Subscripts to α_s and α_v must be used to denote the method of particle size measurement. Hence for an irregular particle whose size is described in terms of the dimensions of a projected area diameter x_a, the geometric volume shape factor α_v can be symbolized as α_{va}, and the surface shape factor α_s as α_{sa}.

Measurement of the two-dimensional quantity of area can be obtained from the projected microscopic image of the particle, while the three-dimensional quantity (volume) can be measured from either a sedimentation or an electrical sensing zone technique. The electrical sensing zone method is, however, the preferred method for particle volume measurement nowadays.

When the characteristic dimension of an irregularly shaped particle is the projected area diameter x_a, the surface of that irregularly shaped particle can thus be symbolized as $\alpha_{sa}x_a^2$, where the subscript ''s'' in the shape factor α_{sa} denotes a surface shape factor and the subscript ''a'' is related to the projected area diameter x_a. This shape factor is multiplied by the square of the particle size measurement of the particle's projected area diameter, x_a, which is obtained from microscopy.

When the measured dimension is that of a sphere with the same surface area as an irregular particle then, by definition, the surface area of that sphere is equivalent to πd_s^2 or πx_s^2. Likewise, from the volume viewpoint, if the volume of an irregularly shaped particle is $\alpha_{va}x_a^3$, with x_a as the diameter of the irregularly shaped particle, then the volume of a sphere with diameter x_v is mathematically equivalent to $\pi x_v^3/6$. The surface area and volume shape factors of spherical particles α_s and α_v are thus numerically equal to 3.14 (π) and 0.52 ($\pi/6$) respectively. It has been found empirically[66] that for irregular and nonuniformly shaped particles the ratio V/x^3, where V is the average particle volume and x is the mean particle size, remains sensibly constant for various grades of particles. It has also been found empirically that the ratio S/x^2, where S is the average particle surface area and x is the mean particle size, remains sensibly constant for different sizes of the same material. It is thus possible, at times, to speak of an average particle shape within an assembly of particles, although variations in particle shape with size have been found for some processed and powdered materials.[91] However, such theoretical considerations, although of academic interest, had little or no application in particle processing for many years.

The practical application of shape analysis was initially addressed when Davies[92] stated that since particle shape information was needed to describe the behavior of particles in many industries in which particles were mixed, reacted, stored or transported, and although the main parameters still remained particle size, particle size distribution, density, and surface interactions within complex particle processes, for the purposes of clarity, particle shape should be represented by:

1. the general particle form, by an aspect ratio, a proportionality constant or a shape factor;
2. the surface topography, by roughness, angularity or roundness;
3. or a combination of the previous two categories.

Prior to Davies' practical recognition of the value of particle shape factors within industrial processing, Heywood[93] had derived an expression for the shape of a particle in terms of the general geometric form of an irregular particle from the ratio of length, L, breadth, B, and thickness, T (Figure 7). To separate the dimensional proportions of the particle, from the geometric shape of the particle, Heywood used the ratios of elongation, n (ratio L/B) and flatness, m (ratio B/T), together with a term defined as the equidimensional shape factor, α_0.

The volume shape factor of an irregular particle, α_v, could therefore be represented in part by the factor α_0 and also by the ratios of the elongation and flatness ratios, n and m respectively, which characterized the influence of the dimensions of the particle on the particle shape, as shown in Equation (11).

$$\alpha_v = \frac{\alpha_0}{m\sqrt{n}} \tag{11}$$

Figure 7 Heywood's shape characteristics for an irregular particle.

From a variety of known geometric shapes, and for irregularly shaped particles with known surface shape factors α_s, Heywood[23,94] deduced the relationships for particle shape as shown in Equation (12).

$$\alpha_s = 1.57 + C\left(\frac{\alpha_0}{m}\right)^{4/3}\left(\frac{n+1}{n}\right) \tag{12}$$

Combined with Equation (11), this could be written as shown in Equation (13)

$$\alpha_s = 1.57 + C\alpha_v^{4/3}\left(\frac{n+1}{n^{1/3}}\right) \tag{13}$$

where the shape coefficients α_0 and C can be determined experimentally (Tables 12 and 13). Values of L, B and T can easily be obtained using an automatic scanning microscope and software. This approach to shape recognition has been used by Church,[95] Dwyer et al.[96] and Mandelbrot[97] to obtain relationships between measured particle and linear diameters and other particle parameters, for a collection of powders.

A disadvantage of Heywood's elongation ratio is that as an irregularly shaped particle becomes more elongated and the breadth becomes smaller, the elongation ratio tends to an infinite value. Heywood's elongation ratio has fortunately also been defined, in different terminology, as an aspect ratio which is the ratio of the length of an irregular particle divided by the width of the particle

Table 12 Shape coefficients for some geometric and nongeometric shapes

Shape group	α_0	C	$\alpha_0 C^{4/3}$
Geometric form			
Tetrahedral	0.328	4.36	0.986
Cubical	0.696	2.55	1.571
Spherical	0.524	1.86	0.712
Approximate form			
Angular			
Tetrahedral	0.38	3.3	0.91
Prismoidal	0.47	3.0	1.10
Subangular	0.51	2.6	1.06
Rounded	0.54	2.1	0.0

Table 13 Typical values for the shape coefficients of irregular particles of various shapes

Material	α_0	α_s	ψ
Rounded particles, water-worn sand	0.32–0.41	2.7–3.4	0.817
Angular particles, pulverized minerals	0.20–0.28	2.5–3.2	0.655
Flaky particles, talc, gypsum	0.12–0.16	2.0–2.8	0.543
Thin flakes, mica, graphite	0.01–0.03	1.6–1.7	0.216

profile at right angles to the length measurement (L/W). Kaye and Clark[98] suggested that a more acceptable and possibly more practical ratio would be the chunkiness ratio, W/L or B/L, which is the reciprocal of Heywood's elongation ratio or the aspect ratio of the irregular particle. The chunkiness ratio thus gives a numerical range from zero to unity (instead of unity to infinity), as the breadth of the irregular particle decreases with length.

To distinguish between cubes and spheres, which have linear mono-dimensional values, an alternative technique is required, which involves the comparison of an irregularly shaped particle with a more symmetrical body. To these ends, comparison of the degree of asymmetry of an irregular shaped particle with that of a symmetrical body was proposed by Wadell for petrological and geological powdered soil samples. Wadell[99–101] defined the shape of an irregularly shaped particle as having either sphericity, ψ, or roundness, P. Sphericity was defined as the ratio of the surface area of a sphere that has the same volume as an irregular particle, to the actual surface area of the irregular particle. This can be expressed algebraically as shown in Equation (14)

$$\psi = \frac{\pi d_v^2}{\pi d_s^2} \tag{14}$$

but can also be expressed in a more practical manner as the working formula shown in Equation (15).

$$\psi = \frac{d_c}{D_c} = \frac{\text{Diameter of a circle equal in area to the projected area of a particle in a stable plane}}{\text{Diameter of the smaller circle circumscribing the projection of the particle}} \tag{15}$$

Treasure[102] showed the interdependence of shape factors using the relationship of the surface coefficient, α_s, the Heywood equidimensional shape factor, α_0, and Wadell's sphericity (Table 13), as shown in Equation (16).

$$\psi = 4.38\frac{\alpha_0^{2/3}}{\alpha_s} \tag{16}$$

Wadell's roundness can be obtained by measuring the radius of curvature (r) of each projection in the perimeter of an irregular particle. The sum of these radii can then be related to the radius of the maximum inscribed circle (R) by Equation (17)

$$P = \sum \frac{r/R}{N} \tag{17}$$

where N is the number of projections measured (Figure 8). As the corners of a particle are worn down, the radius of curvature, r, tends to R and thus P tends to unity.

Figure 8 Wadell's shape characteristics for an irregular particle. (a) Two particles with identical roundness ($P = 1$) but different form; (b) Wadell's roundness for an irregularly shaped particle; (c) two particles with $P = 0$ but with different form and angularity.

Table 14 Shape coefficients for sections of a cube

Relative dimensions of cube	α_0	α_s	ψ
Thickness = breadth	0.696	4.71	0.806
Thickness = breadth/2	0.348	3.14	0.761
Thickness = breadth/10	0.070	1.88	0.434
Thickness = breadth/100	0.007	1.60	0.110
Thickness = 0	0.0	1.57	0.0

Wadell's roundness factor can be used to distinguish between the form of the particle and the roundness or surface perimeter, sometimes termed the roughness, of a particle. Thus Wadell's roundness ratio is, at the moment, favored instead of Wadell's sphericity. This is because of the insensitivity of Wadell's sphericity ratio, which requires large changes in relative particle proportional dimensions of length and breadth to thickness in order to produce significant changes in Wadell's sphericity, ψ (Table 14).

Any shape factor that attempts to visualize and enumerate the inherent roughness of the surface of most real powdered materials is dependent on the measured fineness or surface area of particles, because the evaluation of the surface area or perimeter of an irregularly shaped particle changes in accordance with the measurement technique used to characterize an assembly of irregularly shaped particles. This can be illustrated by the sphericity value of a porous spherical

particle, which is relatively low in numerical value and may therefore be indistinguishable from the sphericity of a smooth but irregular and highly convoluted particle. The area and perimeter of an irregular particle were used by Hausner,[103] who encompassed the complicated irregular shape of a particle image within a rectangle. The dimensional characteristics measured are the side lengths of the rectangle, a and b, the projected area of the particle's image, A, and the circumference of this area, C'. Since the cross-sectional area and circumference of a spherical particle are $A = d^2\pi/4$ and $C' = \mathrm{d}\pi$, respectively, the relationship $C'^2 = 4\pi A$ exists. Therefore for a spherical particle, which gives the minimum surface area for a given volume, a Hausner shape factor can be defined as shown in Equation (18), and has a value of unity for a spherical particle.

$$Z = \frac{C'^2}{12.6A} \tag{18}$$

Since automatic image analyzers with appropriate computer software can now rapidly measure particle surface area (with and without porosity), perimeter, Feret's diameter, longest chord length and number of particles (Figure 3), numerical values of the various shapes and forms of irregular particles can now be readily obtained from ratios of these various image parameters.[95,96]

5.1.2 *Signature Waveforms of Irregular Particles*

With the advent and development of automated microscope systems linked into and coupled with computers, the description of irregular particle shapes and the characterization of profiles by complex mathematical functions has now become available. Schwartz and Shane[104] were the first to describe a two-dimensional profile of an irregularly shaped particle by a geometric signature waveform that could undergo Fourier analysis.[105] The signature waveform was generated by locating, at a central position within the particle profile, a vector that touched the outline profile of the particle. The magnitude of the vector, at various angles when moved around the irregular profile, could either produce a graph of magnitude against angle or be treated as a continuous periodic harmonic waveform (Figure 6). The complex particle signature waveform could then be broken down by Fourier analysis[105–107] into a list that commonly used the first five harmonics in a Fourier series of the simple harmonic wave to uniquely characterize the shape of the irregular particles. A list of the Fourier harmonic series within the complex signature waveform gave a dimensionless shape description of the particle. The central location of the vector could be the center of the smallest circle inscribing the particle, as in the work of Schwartz and Shane, or could be at the center of gravity of the particle.[108,109] The higher harmonics (>5) were believed to give an indication of the texture of the irregular particle. Kaye[110] reviewed the work on Fourier shape analysis and found that the geometric signature method was, in reality, only of use for relatively rounded materials, such as geological fluvial sediments and spray-condensed metals or spray-dried products. Kaye, following the work of Austin et al.,[111] used the signature waveform methodology in combination with slip-chord analysis to separate the edges of an irregular particle image and therefore introduced a new concept to the armory of shape analysis. This concept, which is termed the angular facet signature waveform, is now used in the shape characterization of abrasives and comminuted materials.[113]

5.1.3 *Fractal Geometry of Rugged Irregular Particles*

Mandelbrot[87] used fractal geometry to describe the ability of a convoluted line to fill two-dimensional space. A straight line, on a flat piece of paper, without any ''ups and downs'' and without ''wiggles'' has a topological dimension of unity. As the ''straight'' line becomes more irregular in shape, wiggles up and down on the flat piece of paper, and has an ''irregular wavelike'' form, it occupies more two-dimensional space than a straight line. The fractal dimension thus becomes greater than one because of this irregular waveform or ruggedness of the line (Figure 6). The extended irregularities of the boundary of an irregular particle can be likened to a convoluted line and fractal geometry. The fractal dimension of the boundary of irregularly shaped profiles can thus be applied, as an alternative mathematical method, to obtain an index of ruggedness or texture of irregularly shaped particles. The length of a convoluted curve can be estimated from the number of steps required to traverse a convoluted curve. As the step size decreases, the zig-zag stepped curve follows the convoluted curve being measured more closely, until eventually a constant value for the length of the convoluted curve is reached (Figure 9).

Mandelbrot[97] showed that for a fractal curve a plot of the logarithm of the estimated length of a convoluted curve against the logarithm of the step size used gave a linear relationship which extrapolated to an infinite length. The slope of the log–log plot gives a quantity $(1 - D)$ which is defined as the fractal dimension of the rugged boundary curve of an irregular particle. The Mandelbrot fractal dimension is termed a fractal which has a number between 1 and 2 and which can be used to describe the structure or shape of an irregular profile. Flook[113] used fractal dimensions to characterize the texture and structure of geometrically constructed model particles and the profiles of carbon black aggregates. He found that for carbon black aggregates the plot of

Figure 9 Fractal geometry of a rugged irregular particle. The two fractal step sizes, λ_1 and λ_2, are expressed in terms of the Feret's diameter, d_F, of the irregular particle as 0.27 d_F and 0.13 d_F, respectively. The log graph shows the normalized values of the perimeter, $P(\lambda)/d_F$, versus the normalized step length, λ/d_F, to give a slope of $(1 - D)$ which is the fractal dimension of the rugged irregular particle. $P(\lambda)$, perimeter; λ step length; d_F, Feret's diameter; K, constant.

logarithmic perimeter length against logarithmic step size showed a departure from linearity at large and small step sizes. At small step sizes the fractal dimension (from the slope of the log–log plot) was dominated by the structure of the subunit, while at large step sizes it was affected by the coarse structure of the agglomerate. Flook concluded that it was practical to use fractal dimensional measurements to characterize the textured and structured profiles of a wide variety of materials.

5.2 Indirect Measurement of Particle Shape

5.2.1 Off-line Shape Characterization

One of the inherent restrictions in the characterization of particle size is that the measurement of a particle dimension is dependent upon the physical criterion used in the measurement technique. An irregular particle will be found to have different diameters when characterized by sieve analysis, sedimentation and an electrical sensing zone technique. The difference between the measured sizes can therefore be advantageous in shape recognition, and the factor of proportionality between the particle sizes determined by different analysis techniques can be regarded as a shape factor. BS 3406 Parts 2, 3, and 4 (1963) states that a particle found by sieve analysis to have a diameter of 75 μm may have a mean projected diameter of 105 μm or a mean Stokes diameter of 70.5 μm. BS 4359 Part 3 (1970), Appendix B tabulates calculated and experimental values of surface, volume and specific-surface coefficients (shape factors) for various dimensional forms and irregular particle shapes. These shape factors were obtained from sieving, permeability, sedimentation, electrical sensing zone and light extinction methods of particle size and surface area measurements. In all cases the numerical values of 3.14, 0.52 and 6.0 for α_{sv}, α_{vv} and α_{svv}, respectively, applicable to spherical forms, are exceeded for nonspherical or irregularly shaped particles over a range of sizes from 2000 μm to 0.5 μm.

From Heywood's[93] flatness ratio ($m = B/T$) and elongation ratio ($n = L/B$), a relationship between the shape and sieve characteristics of a powder can be established, as shown in Equation (19)

$$x_a = 0.98 \left\{ \frac{2nm^2}{m^2 + 1} \right\} x_t \qquad (19)$$

where x_a and x_t are the projected area and sieve diameter respectively for various values of m and n.

Nystrom and Stanley-Wood[114,115] described a ring gap sizer, initially used for the characterization of fragile explosive materials, which could measure uniquely the thickness of particles, as opposed to an intermediate diameter between length and thickness as obtained by sieve classification. The geometric mean particle size obtained from the ring gap sizer was within 7% of the mean thickness of particles measured by microscopy. Comparison between the ring gap sizer diameter and the dry sieve diameter could thus be used to establish shape factors of free-flowing materials.

Pilpel[116] showed that the shape of small particles obtained by comminution is dependent upon the method of size reduction. Micronized pigments are often less irregular and more spherical in shape than particles which have been repeatedly fractured and sheared by attrition. Table 15 shows the shape factors for several micronized or fractured materials. As the shape factor – the ratio of the calculated surface area obtained from electron microscopy to the BET measured surface area – approaches unity, it indicates a particle with a more spherical form. The effect of size and shape on the flow and failure properties of penicillin powders, which have an angular prismoidal form, was shown by Walton and Pilpel[118] to affect the bulk powder characteristics of cohesion, tensile strength, internal friction and failure factors.

5.2.2 On-line Shape Characterization

In-line and on-line techniques for product engineering and the characterization of industrial powder processes continue to attract the attention and demands of industry because particles passing through any physico-chemical

Table 15 Effect of micronization on the shape of pigment particles

Pigment	Measured surface area ($m^2\ g^{-1}$)	Calculated surface area ($m^2\ g^{-1}$)	Shape factor
Prussian blue	61.3	2.3	0.04
Prussian blue, micronized	58.9	12.7	0.23
Red iron oxide	7.6	3.4	0.44
Red iron oxide, micronized	7.3	4.9	0.68
Burnt amber	138	1.2	0.01
Burnt amber, micronized	94	5.0	0.05
Yellow iron oxide	17.6	1.4	0.08
Yellow iron oxide, micronized	17.7	2.5	0.14

process affect the performance of the process and the specification of the product. For most operations the two most important parameters in process monitoring and control are particle size and morphology. With recent advances in sensor technology it is now possible to implement both size measurement and shape morphology characterization simultaneously. This can be done using two separate units,[118] one for size and the other for shape,[119] or a single unit[120–122] which can, by laser light illumination, produce both a particle size distribution from a flowing stream of particles, using a time-of-flight (TOF) or time-of-transition (TOT) technique, and also a morphological particle shape characteristic.

Although light-scattering techniques are not commonly used for particle shape classification there is, within the scattering signature from the scattered light intensities obtained from the particle size distribution, encoded information from which it should be possible to infer the shape of particles. By changing the geometric shape of the photodetectors from a series of semicircular concentric detectors to an array of wedge-shaped detectors in a segmented ring, the shape of particles may be measured.[123] To record the particle shape information from the scattered light, the classical laser diffraction detection system (which uses semi-ring-shaped detectors to collect the radial spatial frequencies or intensities of the particle field), has to be changed to include wedge-shaped photodetectors which collect encoded particle shape information in the form of azimuthal spatial intensity frequencies. The influence of shape on size measurement by light blockage and the characterization of plate-like particles has been appraised for rapid response instrumentation and in modified on-line light techniques.[124]

It is now currently accepted that a combination of both size and shape measurements will lead the way forward to the characterization of mixed particle species, complex designed particles and multifunctional agglomerated systems of varied size, shape, and mix.[125]

6 NATIONAL AND INTERNATIONAL STANDARDS AND REFERENCE MATERIALS

6.1 National and International Standards

For the purpose of scientific communication, and to avoid disputes in commerce, industry and legislation, it has long been recognized that great value can be derived from using measurements directly related to fundamental standards. Most physical, physico-chemical and chemical primary and fundamental units have been defined by scientific experts, and are maintained under specific conditions that permit little or no variation in the value of the unit. In the field of powder technology, with the proliferation of particle size measurement techniques, there are several ways that an irregularly shaped mass of material can be characterized and sized. The method generally used at present is known as the equivalent sphere diameter, but more complex particle parameters may be used in the future as advances occur in the in situ recognition of assemblies of particles within industrial particle processing operations. It may be beneficial one day to characterize particulate matter obtained from a production process in terms of the purpose for which the particle or powder has be produced rather than to undertake the arduous task of sizing. Scarlett[126] and Leschonski[127] both appraised the necessity to size particles using equivalent sphere diameters. The characterization and sizing of particles in industries dealing with powdered material is generally only used to specify and maintain product functionality, and not to generate products of a certain size. As long as the product functionality (be it flowability, solubility, taste or drug efficacy) is maintained within specifications, then size is a secondary parameter. With the diversity of particle-sizing techniques readily available it may therefore be advantageous to measure the appropriate size of the particle using a physical property as closely related to the product functionality property as possible. There is therefore a need to calibrate powder measurement techniques to measure reconcilable particle properties closely related to the product properties, which at the present time happens to be the reconcilable property of size. Reference materials are then required, together with the careful standardization of a few basic techniques, to achieve confident particle sizing.

Leschonski[127] has commented that the measurement of size and size distribution of irregularly shaped particles ranging from a tenth of a micrometer to

several centimeters is, and presumably always will be, a difficult task. Whichever method is used for particle size measurement, there are two prerequisites which have to be accepted by all powder analysts because of the truisms of powder technology. The first prerequisite is that whichever particle size measurement technique is selected there has to be a recognized and a commonly accepted protocol or procedure, and therefore ultimately an agreed national or international standardized technique, to determine the particle size metrology and to ensure that one analyst's results will tally with another analyst's results. Confidence in the measurement technique chosen and the instrument used, from the simplest to the most sophisticated, is enhanced when the measurement can be related to a recognizable standard. Traceability may not be essential for the simplest in-house routine quality control tests, provided that the instrument is verified to give consistent results in terms of reproducibility with a selected standard or possibly a certified material.

This consensual standard method of analysis need not give an absolute measure of size, but any technique of size measurement should (and ultimately legislation may make this mandatory) be based on measurements where all the physical criteria measured are traceable directly to the international standards of mass, length and time and not derived from a second-order effect, unless the alternative measurement technique has been calibrated by certified reference materials and therefore becomes a traceable secondary standard. The second prerequisite is to have available reference materials (section 6.2), which in the special case of powder technologists tend to be reference powders of known particle size and particle size distribution. These reference powders can then aid the verification of the first prerequisite.

Standardization of the measuring methods available to the powder technologist is becoming, because of the global advances in powder manufacturing and chemical processing, more and more international rather than national. However, a situation may arise where a more sophisticated national standard may be created by an advanced technological nation, but not accepted at an international level by other less technologically advanced nations. Nowadays national standards are being harmonized within the framework of the European Community and also at an international level. National standard organizations still update current standards and tend to initiate new working standards as the processes of powder handling, characterization and particle measurement undergo innovation. Table 16 lists some of the standardization institutes that actively promote drafts and renew existing standards for the powder technological community, while Table 17 gives details of the current published British and German standards relevant to powder technology.

Many national standards are, at present, rapidly being superseded at an international level. The ISO has established a technical committee (TC 24) to standardize equipment and methods used in the size classification of particulate materials in solid or liquid states. TC 24 is divided into several subcommittees interested in test sieves, test sieving (SC 1); industrial wire screens (SC 3); and sizing by methods other than sieving (SC 4).

The work groups (WG) within SC 4 are listed in Table 10. It can be seen from the titles of the work groups that the SC 4 group has a very large remit, with the responsibility of attempting to standardize a wide range of particle size, powder surface area and powdered material porosity measurement techniques. Some of the standardization committees working in the field of powder technology are also listed in Table 10. The members of TC 24/SC 4 are Australia, Belgium, China, Finland, France, Germany, Israel, Japan, Norway, Sweden, The Netherlands, the UK and the USA, who nominate delegates to work in various powder technological fields. Table 10 also shows some of the approved and published standards together with the progress of other work groups within TC 24/SC 4.

6.2 Reference Materials

In all particle size instruments available at present, except microscopes, an assessment is made of particle size distribution by recording values of a size-dependent physical property analogous to particle size. While this is not ideal it has long been accepted that if the limitations can be assessed by users and recipients of the data obtained

from the range of size-dependent physical criteria used in present day instruments, and possible measurement techniques of the future, then a nonabsolute size measurement of irregularly shaped particles is justifiable. It is thus incumbent upon designers, vendors and users of instruments to identify the assumptions made in relating the results obtained from any instrumention to the fundamental units of length, mass or time, or other mathematically derived or correlated units. The mechanism by which the above relationship is achieved within the instrument is known as calibration.[25]

Leschonski, foreseeing the need for instrument calibration in terms of size and the measurement of reference materials of known size certified on the basis of traceability, advocated that the most desirable approach to describe size would be that of the volume or, if the density of the material is accurately known, the mass of the particle or particles. This has resulted in the certification, by BCR, of irregularly shaped solids (quartz) over a range of distributed sizes using the off-line techniques of sieving (160–630 μm) and sedimentation (0.35–90 μm) and a range of nitrogen BET specific surface area reference materials.[128] Certified mono-sized polymer microspheres in discrete sizes from 20 nm to 2000 μm are also commercially available from BCR and NIST.

6.2.1 Calibration and Traceability

Calibration can take many forms depending upon the nature of the measurements being made. In microscopy a graticule is examined concurrently with a stage micrometer that has been graduated in authenticated linear units, traceable to primary standards, by a verified standard procedure. Providing that the conditions of examination are unchanged, the graticule can then be used to make ''absolute'' measurements on the images of objects of unknown size.

In some other particle sizing instrumention, spherical latex particles of known and verified uniform size can be used, so that the results produced by instruments such as laser light scattering and electrozone sensing instruments coincide with the verified values. Calibration materials or calibrants used with such instrumentation tend to consist of populations of particles whose distributions have been determined by a method that has been traceably calibrated and validated. The efficacy of a spherical calibration procedure is shape sensitive. Since a large percentage of calibration methods depend upon spherical calibrants, few problems are likely to arise if unknown test samples comprising only spherical particles are analyzed. However, since only a small percentage of industrial powdered samples exclusively consist of spherical particles a judgment has to be made as to the acceptability of the calibration in relation to the shape, or more likely shapes, present in the samples analyzed.

Whenever a device is calibrated by a user or a manufacturer it should be calibrated using suitable internationally certified reference standards, or secondary standards which are directly traceable to those international standards. For good laboratory practice, the whole measurement and calibration process must also be validated. This requires that objective evidence is established to show that the measurement process consistently produces results to within required specifications, with consideration being given to all procedural and analytical variations. When certified material that has a traceable source and pedigree is presented to another instrument that does not have the same physical basis of particle size measurement or the same size-dependent physical property, then a comparison is taking place and the certified material is acting as a reference material (Table 18).

However, if the certified material is used to adjust the output of the instrument to the values consensually accepted from the material then the instrument has been calibrated. A reference material may be used for the calibration and checking of any instrument used for particle sizing, but certified material is usually only certified for one or two fundamental methods. Care must be taken in calibrating and checking other particle sizing instruments that do not use the same physical principles as those upon which the certified material was certified. In general, materials that have a particle size distribution tend to be regarded as reference materials, while mono-sized materials tend to be used to calibrate instruments. Traceable calibrants and control reference materials (Tables 19 and 20) are available from, for example, BCR. Evidence of traceability must always be supported by a trail of documentation.

6.2.2 Validation and Verification

It is likely that all particle-sizing instruments will require both the traceable calibrant and the reference material approaches, in which different proportions of a series of mono-sized particulate material are mixed together to assess the parameters of reproducibility, repeatability, accuracy and possibly sensitivity of the instrument.

The validity of the software that nowadays governs and controls many particle sizing instruments will also have to be addressed, so that there is now a need to have three levels to test particle-sizing instruments:

1. verification of the software routines used to interpret the measured size-dependent physical criterion used to size irregular particles;
2. physical tests to ascertain the correctness of the size-dependent physical criterion measured with traceability;

Table 18 Distributors of reference materials

Acronym	Contact Information

		1.70	Width	
		1.00	Depth	
	Aerodynamic diameter	3.78	Minor axis	
	Aerodynamic diameter	4.51	Major axis	
AEA 1004[a]	AEA Technology	0.1, 0.2, 0.5		Cocktail of spherical polymer latex particles
AEA 1004[a]	AEA Technology	0.2, 0.5, 1.0		Cocktail of spherical polymer latex particles
AEA 1004[a]	AEA Technology	1.0, 2.0, 5.0		Cocktail of spherical polymer latex particles

[a] Number concentration: particles per mL in a 10 mL volume is 4×10^8.

3. certified powdered materials with known sizes and size distributions to verify and confirm that the particles displayed by the instrument are in reality the physical particle sizes introduced into the instrument.

One way of providing confidence and acceptability in the particle sizes measured from the diverse range of particle size instruments available is by verification, which can be defined as: ''the examination and provision of objective documentary evidence that specified requirements have been fulfilled''. If the verification can be extended to demonstrate that an instrument or process is suitable for fulfilling the requirement of a specific intended use, then that instrument or process is said to be validated.

LIST OF SYMBOLS

A	Projected area of an irregularly shaped particle image
B	Breadth of an irregularly shaped particle
C	Sampling constant, which is a function of a material's properties and which can be determined
C	Shape constant which can be determined experimentally (section 5.1)
C'	Circumference of the projected area of a particle's image
d	Size of square mesh sieve to retain 5% of the particles or a specified percentage of a specified size range of particles
d_d	Drag diameter of an irregularly shaped particle
d_f	Free-fall diameter of an irregularly shaped particle
d_s	Equivalent surface area diameter for an irregularly shaped particle
d_{St}	Stokes diameter of an irregularly shaped particle
d_t	Sieve size diameter of an irregularly shaped particle
d_v	Equivalent volume area diameter of an irregularly shaped particle
k	Power of the moment of particle size x or the kth moment of a density distribution, which is related to the method used to calculate the average size of the particle within the distribution
L	Length of an irregularly shaped particle
m	Sample weight used in sampling (section 2.2)
m	Heywood's flatness ratio (ratio B/T)

m	Slope of the Gaudin–Schuman distribution (section 3.3.1)
M	Moment of a distribution
n	Heywood's elongation ratio (ratio L/B)
n	Slope of the Rosin–Rammler–Sperling–Bennet distribution (section 3.3.2)
N	Number of projections measured in Wadell's roundness
P	Wadell's roundness
q	Particle density distribution
$q_r(x)\,dx$	Fraction of particles in the size range $(x - dx)/2$ and $(x + dx)/2$.
Q	Cumulative particle density distribution
$Q_r\,(x)$	Cumulative particle density distribution of size x
r	Quantity of a particle distribution or type of statistical distribution
$R\,(x)$	Rosin–Rammler–Sperling–Bennet distribution
s^2(FE)	Variance of fundamental error of $(a_s - a_b)/a_b$ where a_s and a_b are content values of sample and bulk batch respectively.
S	Average particle surface area
T	Thickness of an irregularly shaped particle
V	Average volume of an irregularly shaped particle
V_{a-t} curve	Linear relationship, passing through the origin, between the volume adsorbed (V_a) and the thickness of the multilayer adsorbed on the nonporous solid (t)
x	Size characteristic of an irregularly shaped particle
x_a, x_t	Projected area and sieve diameter of an irregularly shaped particle
$x_{k,r}$	Average particle size/diameter
x_{max}, x_{min}	Largest and smallest particle sizes in a distribution
x_n	Equivalent mesh diameter
x_s	Equivalent surface diameter
x_v	Equivalent volume diameter
x_w	Equivalent settling diameter at either high or low Reynolds numbers
x'	Particle size of x corresponding to a cumulative percentage $Q_3(x)$ equal to an undersize of 63.2% or an oversize of 36.8%
$x_{1,2}$	Average length-surface or average volume-surface diameter of an irregularly shaped particle
x_{84}, x_{50}, x_{16}	Values of size at which $Q_r\,(x)$ is 84%, 50% and 16% respectively
z	Equivalent to the percentage of an arithmetic particle size distribution at a specific size x and at a size which occurs at 50% of the distribution ($z = (x - x_{50,r})/2$). For logarithmic size distributions $z = \ln(x/x_{50,r})$.
Z	Hausner shape factor
$(1 - D)$	The fractal dimension of the rugged boundary curve of an irregular particle
α	Shape factor
α_0	Equidimensional shape factor
α_s	Sing's 'alpha s' plot
α_s, α_v	Shape factors which denote the method of particle size measurement
α_v	Volume shape factor of an irregular particle
ψ	Wadell's sphericity shape factor

ABBREVIATIONS AND ACRONYMS

BCR	Bureau Communautaire de Réference
BDDT	Brunauer–Deming–Deming–Teller
BET	Brunauer–Emmett–Teller
BS	British Standard
FE	Fundamental Error

*Millions of tons per year of submicron particles are produced in industrial processes around the world. They are also referred to as nanoparticles, colloids, latices, polymer dispersions, mini-emulsions or micro-emulsions. These solid or liquid particles, which are mostly dispersed in an aqueous medium, have a diameter (*D*) in the* $10 < D < 3000$ *nm range. They are used as dyes and pigments, in paints, adhesives and coatings applied to paper, as impact modifiers in plastics, as catalysts, in cosmetic and photographic emulsions, metal sols and electrodeposition coatings applied to automobiles, as excipients for pharmaceuticals, etc.*

Most of the valuable practical properties of these nanoparticle dispersions/emulsions result from their extremely small size and their high specific surface area. This implies that it is essential to be able to control and measure the particle size in order to produce nanoparticle systems of consistent quality. The particle size distribution is just as important as the average particle diameter. The practical consequences of changing from a very narrow to a very broad particle size distribution with the same average diameter can be quite dramatic in many applications. For example, the viscosity of a high-solid polymer latex will decrease, the impact strength of plastic material will increase, surfaces coated with emulsion paints will become more level, etc.

Many methods, such as light scattering, electron microscopy, field flow fractionation (FFF), capillary hydrodynamic chromatography and ultracentrifugation, are used to measure the average particle diameters and overall particle size distribution of nanoparticles. Analytical ultracentrifugation (AUC) is the most versatile method with the broadest diameter range (1–5000 nm) and the highest resolution. The nanoparticles are forced to move through a predominantly aqueous medium inside an AUC measuring cell under a centrifugal force of 500–500 000 × g *(rotor speed 100–60 000 rpm). Sedimentation causes fractionation to take place, because the larger particles move faster. The sedimentation velocities* s_i *of the different fractions* i *are measured with refractive index, ultraviolet (UV)-absorption or light scattering/turbidity detectors. The diameters* D_i *of the different fractions can be calculated from the difference in* s_i*, i.e. the complete particle size distribution, according to Stokes' law. The resolution of the AUC method is so high because, according to Stokes,* s_i *is proportional to the square of* D_i*. The AUC particle size distribution method can give spurious results if* D *is too high, i.e. if the particles form a sediment too quickly or if they display a broad chemical heterogeneity (i.e. no uniform particle density).*

1 INTRODUCTION

Submicron or nanoparticles with diameters in the $10 < D < 3000$ nm range are produced and consumed in large quantities around the world, mostly in the form of aqueous dispersions or emulsions. Important applications for polymer dispersions (latices) are in paints, papermaking and adhesives, for modifying the impact strength of plastics and in the production of synthetic rubber. Their particle size distribution is one of their most important characteristics, because it affects many of their practical properties. Many different techniques have been developed to measure particle size distribution, such as light scattering, hydrodynamic chromatography, electron microscopy, sedimentation and FFF and AUC. The AUC method is the most versatile, high-resolution, relatively fast technique,[1] and it also covers the greatest diameter range ($1 < D < 5000$ nm).

Three AUC methods are described in this paper,

1. standard particle size distribution,
2. H_2O/D_2O sedimentation analysis (which is also used to measure particle densities)
3. the coupling method (which is used to measure extremely broad particle size distributions).

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

All three methods are based on Stokes' equation and on Mie's light scattering theory, which means that light scattering takes place inside the AUC apparatus. After briefly recounting the history of the AUC method, we will go on to look at the experimental set-up with an eight-cell rotor and multiplexer and its physical principles, H_2O/D_2O sedimentation analysis and the coupling particle size distribution method with the aid of some illustrative examples. We will then consider future prospects by looking at a new two-laser-beam technique and AUC particle size distribution measurements of extremely small inorganic colloids (1–20 nm) with angstrom resolution, using very high rotor speeds and refractive index or absorption optics detectors.

2 HISTORY OF ULTRACENTRIFUGATION PARTICLE SIZE ANALYSIS

The first AUC particle size distribution measurements on colloidal particles were performed in 1924 by Rinde and Svedberg.[2,3] (Svedberg invented AUC, and was awarded the 1926 Nobel Prize in Chemistry for his work.) They analyzed gold sols, measured their sedimentation velocity s, and used the results to calculate the diameter D of the gold particles using Stokes' law. Nichols, Kraemer and Bailey[4] later improved the initial AUC particle size distribution set-up. Cantow[5] was the first to measure polymer dispersions with a turbidity detector inside the AUC apparatus, using Mie's light scattering theory[6] of spherical-shaped colloidal particles to calculate the correct mass percentages m_i of the different particle fractions. Later, Scholtan and Lange[7] developed another, very simple AUC particle size distribution set-up which employed a small one-beam turbidity/light scattering detector. This set-up was further developed by Mächtle,[8] who introduced the following new features: (1) a change from a single-beam to a double-beam technique; (2) an increase in the measuring capacity by a factor of seven by the introduction of an eight-cell rotor and a multiplexer, which allows simultaneous measurement of seven samples and a reference cell; (3) a modification from the common operation mode using a constant rotor speed N to a new time-dependent operation mode $N(t)$ in which the rotor speed is increased exponentially during each run from $N = 0$ to the maximum speed $N = 40\,000$ rpm within 1 h, always at the same rate. This allows samples containing very small particles of about 10 nm and very large particles of about 3000 nm to be measured in the same run. The multiplexer and $N(t)$ technique were prerequisites for H_2O/D_2O sedimentation analysis[8] and the coupling particle size distribution method.[9,10] Our latest development,[11] the introduction of a parallel two-laser-beam set-up, has increased the resolution and the accuracy of AUC particle size distribution measurements. Extremely small inorganic colloids in the 1–20 nm range have become a new issue over the last three years. Their light scattering is so weak that the turbidity/light scattering detector inside the AUC apparatus cannot be used. Instead modern UV scanners or refractive index detectors (schlieren or interference optics) and constant high rotor speeds are used, as for dissolved macromolecules.[12]

3 EXPERIMENTAL SET-UP

The photograph in Figure 1 shows our AUC set-up outside the rotor chamber. It includes eight measuring cells, an eight-cell rotor and a U-shaped stage, with the laser diode light source above the rotor and a fast photo diode light detector below the rotor. This set-up also contains a preparative ultracentrifuge (Optima XL, Beckman-Coulter, Palo Alto, CA, USA) which we have modified into an analytical ultracentrifuge by installing an analytical eight-cell rotor (Beckman type AN-50 Ti) and simple turbidity/light scattering optics. We have two versions of this turbidity detector, an older one with an incandescent lamp and a photomultiplier as the light source and light-receiving detector, and a newer one with a 670 nm red light laser diode and a very fast photo diode

Figure 1 Laser optical set-up showing rotor and cells, with a laser diode above the rotor, and a photo diode below the rotor.

(see Figure 1). An AUC measuring cell is situated to the right-hand-side of this eight-cell rotor in Figure 1. The centre piece has a thickness of 3 mm and a sector-shaped cut-out. A flat glass window fitted with a gasket is placed on either side and the gap is filled with the nanoparticle dispersion/emulsion to be analyzed by injecting it through a small hole using a syringe.

A schematic diagram of our set-up is shown in Figure 2(a). The turbid dispersion to be analyzed is diluted to about 1 g L^{-1} and placed into the centre section of the 3-mm cell. The lower quartz window of the cell is covered by an apertured stop, in the centre of which is a 0.2-mm wide slit that is arranged perpendicular to the radius of the rotor. The slit picks out a beam from the entering monochromatic light.

The intensity I of this beam, which is reduced by light scattering of the latex particles according to Mie's theory, is registered by the photomultiplier and recorded as a function of the time of travel t. The concentration of the dispersions is selected so as to yield an initial light intensity I_0 of approximately 10% of I_{DM}, the intensity of the pure dispersant. In our newer version, we use a 0.2-mm laser beam, no apertured stop, and a fast photo diode as the light detector.

In a monodisperse latex, all of the particles settle out with exactly the same velocity. This causes the broken one-step curve shown in Figure 2(b) to be obtained, because the intensity jumps from I_0 to I_{DM} at the moment when the sharply defined, sedimenting latex front passes the measuring slit (or the laser beam). The diameter D of the monodisperse particles can be calculated from the measured jump time t by means of Stokes' law.

In the event of a latex having a broad particle size distribution, the particles are fractionated within the sedimenting latex front according to their size, but the latex front now is blurred by large particles running ahead and small particles lagging behind. This gives a broad continuous transition from I_0 to I_{DM} (thick line). If we approximate this transition by plotting a multiple-step curve (fine line), i.e. by superimposing many monodisperse latex fractions, the $I(t)$ curve renders a curve for the integral particle size distribution (Figure 2c). This is obtained by calculating (a) the diameters D_i of the different fractions from their time of travel t_i, by means of Stokes' law, and (b) their mass fractions m_i from the respective light intensity steps ΔI_i by means of Mie's theory. The sum of all m_i values is unity. Details for calculating m_i with Mie's theory are given in the literature.[8,9]

It should be noted that this particle size distribution analysis strictly only works for hard spheres at a standard concentration of about 1 g L^{-1} ($\approx$ case of infinite

Figure 2 (a) Schematic diagram of the measuring set-up and (b) distribution curves. (Reproduced from Mächtle[9] by permission of Wiley-VCH Verlag.)

dilution). For rods or soft spheres, the dependency of the sedimentation velocity on the concentration might cause errors.

The process we have developed is much more complex than the basic procedure outlined here. In fact, we measure seven samples simultaneously, employing a quasi-two-light-beam technique. A schematic diagram of our method is shown in Figure 3. The process is triggered by reference cell 0 which is filled with the pure dispersant (mostly water). The amplitude of the photomultiplier (or photo diode) impulses from measuring cells 1–7 is measured and divided by the amplitude of the impulses from the cell containing only water using a fast electronic device, then digitized for computer processing, and recorded in analog form by an eight-channel recorder as apparently continuous $I(t)$ fractionation curves (for visual checks only). We no longer keep the rotor speed w constant: instead, we increase it exponentially from 0 to 40 000 rpm over 1 or 2 h during each run in order to cover the smallest particles ($D \approx 10$ nm) as well as the largest ones ($D \approx 5000$ nm). This procedure is fully automatic. The ability to measure seven cells simultaneously and to increase the rotor speed exponentially is a precondition for the two methods that will be described later, H_2O/D_2O analysis[8] and the coupling particle size distribution technique.[9]

Figure 3 Schematic diagram of AUC method for determining particle size distribution, with an eight-cell rotor multiplexer set-up. (Reproduced from Mächtle[8] by permission of Wiley-VCH Verlag.)

4 PHYSICAL PRINCIPLES

Figure 4 shows the basic equations for the determination of both the particle diameter D and the particle density ρ by Stokes' law. It also shows two "snapshots" of monodisperse latex particles in the cell, one of them taken at the start of the measurement ($t = 0$), the other one exactly at the point ($t = t_i$) at which the latex front passed across the measuring slit (or laser beam). A differential equation of motion can be calculated from the equilibrium of forces F acting on an arbitrary particle. The solution of the latter is Stokes' square root equation which allows D_i to be calculated from the measured time of travel t_i or, alternatively, from the sedimentation velocity $s_i = \ln((r_s/r)/w^2 t_i)$ if the particle density $\rho_i = \rho_{PM}$ is known. An unknown ρ_{PM} can be determined by measuring the time of travel in a second dispersant of different density ρ_{DM}. We employ heavy water, D_2O, which has a density of $1.10\,g\,cm^{-3}$, as the second medium. With the modified Stokes' equation (Figure 4, bottom), ρ_{PM} can be determined simply from measured times of travel in H_2O and D_2O, and this equation is the basis of the H_2O/D_2O analysis. There are also other methods of measuring the particle density ρ_{PM}: pycnometry, measurement on bulky materials, AUC density gradient techniques and the Paar density balance. It must be emphasized that the differential equation mentioned here can be solved for the case $w =$ constant and for our new mode of operation with $w = f(t)$. In the "classic" square root equation, $w^2 t$ changes to $\int w^2\,dt$, the integral of the time of travel, which is calculated from the measured curve for $w(t)$ using a computer.

The measurement of seven samples simultaneously is demonstrated in Figure 5. We made up a $1\,g\,L^{-1}$ mixture of three monodisperse Dow polystyrene calibration latices with diameters of 176, 312 and 794 nm at a ratio of 40 : 50 : 10% w/w. This mixture was filled into seven different cells and initially measured in the conventional operating mode at a constant rotor speed $N = 4000$ rpm. As a result, we obtained the seven full line $I(t)$ curves. The measurement was then repeated in the new operating mode with N rising exponentially from 0 to 40 000 rpm, which generated the seven broken line $I(t)$ curves. The respective seven three–step curves obtained in both operating modes agree well.

Figure 4 Determination of D and ρ according to Stokes' law. (Reproduced from Mächtle[8] by permission of Wiley-VCH Verlag.)

Figure 5 $I(t)$ curves of seven mixtures of three monodisperse polystyrene calibration latices, 176:312:794 nm (40:50:10% w/w). (Reproduced from Mächtle[8] by permission of Wiley-VCH Verlag.)

Figure 6 $I(\int w^2 \mathrm{d}t)$ curves of seven mixtures of three monodisperse polystyrene calibration latices, 176:312:794 nm (40:50:10% w/w). (Reproduced from Mächtle[8] by permission of Wiley-VCH Verlag.)

If I/I_{DM} is plotted against $\int w^2 \mathrm{d}t$ instead of against t as shown in Figure 6, the seven curves obtained in the conventional operation mode (N = constant) coincide with those obtained in the new operating mode ($0 < N < 40\,000$ rpm). Because the latex particles are chemically homogeneous, we can convert these 14 $I(t)$ curves into 14 particle size distribution curves. The result is shown in Figure 7, where m_i is plotted against D_i. These 14 particle size distribution curves conform within 5% not only in terms of the known diameters D_i (176, 312 and 794 nm) but also in terms of the given mass portions m_i (40, 50 and 10%), thus proving that our design (seven cells measured simultaneously together with a variable N) does work.

5 WATER/DEUTERIUM OXIDE SEDIMENTATION ANALYSIS

However, the method discussed in the previous section only really works if the dispersion is chemically homogeneous (with the density and refractive index of the particles being uniform). We have therefore developed a

Figure 7 AUC particle size distribution curves of seven mixtures of three monodisperse polystyrene calibration latices, 176 : 312 : 794 nm (40 : 50 : 10% w/w). (Reproduced from Mächtle[8] by permission of Wiley-VCH Verlag.)

Figure 8 H_2O/D_2O sedimentation analysis of a polystyrene latex ($D = 155$ nm). (Reproduced from Mächtle[8] by permission of Wiley-VCH Verlag.)

fast H_2O/D_2O sedimentation technique to analyze non-homogeneous dispersions. As an example, Figure 8 shows the results of the H_2O/D_2O analysis of a polystyrene latex in three dispersants with different densities. The unknown highly concentrated dispersion was diluted at a ratio of approximately 1 : 1000 with the three dispersants H_2O ($\rho = 1.00\,g\,cm^{-3}$), D_2O ($\rho = 1.10\,g\,cm^{-3}$), and a 1 : 1 mixture of H_2O and D_2O, and the three corresponding $I(t)$ curves of these diluted dispersions were measured simultaneously. The computer creates horizontal sections at intervals of 10% steps across the three $I(t)$ curves (2% intervals are possible too). It then calculates the particle density ρ and the particle diameter D of the corresponding fraction from the respective three coupled times of travel at each point of intersection with the curve by means of the two Stokes' equations shown in Figure 4. The table on the right-hand-side of Figure 8 shows the density distribution ρ and the particle size distribution D of the unknown dispersion. In this case, ρ is constant ($1.054\,g\,cm^{-3}$). The dispersion is a chemically homogeneous polystyrene latex which is nearly monodisperse, with its diameters varying around 155 nm.

The polymer dispersion analyzed in Figure 9 is markedly bimodal. After as little as 1 h the H_2O/D_2O analysis revealed that the dispersion was a chemically homogeneous latex with a particle density of $0.89\,g\,cm^{-3}$ (because the three coupled $I(t)$ curves can be forced to coincide by linear stretching along the x-axis). It therefore

Figure 9 H_2O/D_2O sedimentation analysis of a polybutadiene latex mixture 115 nm : 350 nm (72 : 28% w/w). The insert shows the three resulting particle size distributions of this mixture in the three media $H_2O/1:1/D_2O$. (Reproduced from Mächtle[8] by permission of Wiley-VCH Verlag.)

Figure 10 H_2O/D_2O sedimentation analysis of a polystyrene–polybutadiene latex mixture (Polystyrene 155 nm : Polybutadiene 115 nm, 12 : 88% w/w). (Reproduced from Mächtle[8] by permission of Wiley-VCH Verlag.)

had to be polybutadiene. The bimodality is caused by the two particle components having different diameters, 115 and 350 nm respectively. We had prepared this dispersion ourselves by mixing polybutadiene particles of diameters 115 nm and 350 nm in a ratio of 72 : 8% w/w. The insert in Figure 9 shows that the resulting three $H_2O/1:1/D_2O$ particle size distributions of this mixture reproduces very well the given mixing ratio.

Figure 10 shows another example. Here the three $I(t)$ curves of an unknown dispersion can not be forced to coincide by linear stretching along the x-axis, therefore it must be chemically inhomogeneous. Indeed we had prepared a mixture of the nearly matching 155-nm diameter polystyrene particles and the 115-nm diameter polybutadiene particles at a ratio of 12 : 88% w/w. Some of the values for ρ and D are reasonable, but some of them are physically absurd and must be disregarded (they are crossed out here). This indicates that we can confirm within 1 h whether an unknown dispersion is chemically homogeneous or inhomogeneous by means of fast H_2O/D_2O analysis, and we are able to decide whether or not it is possible to determine the particle size distribution by AUC. If H_2O/D_2O analysis states that the sample is chemically inhomogeneous, we then use the powerful AUC density gradient technique[8,13,14] to analyze the inhomogeneity in the particle density in a quantitative, detailed manner.

6 COUPLING PARTICLE SIZE DISTRIBUTION TECHNIQUE

Now we will turn our attention away from monodisperse particles and to extremely broad distributed dispersions, for which we use the coupling particle size distribution technique. We prepared a sample with a broad particle size distribution by mixing ten polystyrene dispersions with a narrow distribution, having $D_{50\%}$ diameters from 67 to 1220 nm, in equal portions of 10% w/w each as shown in Figure 11. Figure 11 also shows the $I(t)$ curve obtained by measuring this mixture of components at the standard concentration of 0.35 g L^{-1} (solid line) which gives an initial light intensity of about 5% of I_{DM}. Each component can clearly be distinguished as a single step with the exception of component 10, the smallest one. The $I(t)$ step for the latter is tiny because of its extremely poor light scattering, i.e. it is badly resolved.

Our coupling technique can solve the problem in cases such as these. We measured the ten-component mixture simultaneously in the same AUC run at a ten-times higher concentration, i.e. at 3.5 g L^{-1}. The additional $I(t)$ curve (broken line) that we obtained shows component 10 at high resolution as well as components 9–7, while component 6 can be partially seen. Components 1–5 cannot be seen because their measuring signal is zero. These two $I(t)$ curves can now be coupled mathematically at the two marked points by combining the lower section of the 0.35 g L^{-1} curve with the upper section of the 3.5 g L^{-1} curve (see Mächtle[9] for details).

If we convert the coupled $I(t)$ curve into a curve for the particle size distribution, we obtain the result shown in Figure 12. The bold line is the integral form and the fine line the differential form of the coupling particle size distribution. The differential form demonstrates the excellent resolution of our particle size distribution equipment especially well. All ten components of this extremely broadly distributed dispersion are separated down to the baseline, including the two components at 318 and 356 nm respectively, even though their diameters are only approximately 12% apart. The ''given'' values in the left table of Figure 12 were used to prepare the

Figure 11 $I(t)$ fractionation curves for a mixture of 10 polystyrene latices with narrow particle size distributions. (Reproduced from Mächtle[10] by permission of Wiley-VCH Verlag.)

Figure 13 AUC particle size distribution of a copper phthalocyanine pigment.

dispersion, and the "reproduced" values in the right table were obtained empirically by measuring the mixture of ten components. We were able to reproduce the diameters to within 5% and the proportions of the mixture to within 15%. This shows that our coupling particle size distribution technique works for dispersions with an extremely broad distribution. We also tried to measure the particle size distribution of this ten-component latex mixture by sedimentation FFF,[15] but this method was not able to reproduce the correct mixing ratio. This demonstrates the superiority of the AUC method (see also Lange[1]).

7 EXAMPLES OF ANALYTICAL ULTRACENTRIFUGATION PARTICLE SIZE DISTRIBUTION TECHNIQUE

It should be emphasized that we can measure the size distribution of particles contained in pigment preparations, paints and emulsions as well as those contained in polymer dispersions, that is to say any kind of dispersed microparticles having diameters in the range from 10 to 3000 nm. Nonspherical particles such as ellipsoids, cubes, rods or needles can be also measured, but the measured "diameter" is that of a Stokes-equivalent sphere. The dispersant does not necessarily have to be water. Dispersed particles can be measured in any liquid medium, including organic solvents. This can be demonstrated by a few examples.

Figure 13 shows needle-shaped crystals of a copper phthalocyanine dye used in printing inks together with the particle size distribution curve that we obtained by AUC measurement, yielding Stokes-equivalent sphere diameters of 20–150 nm. We also analyzed the electron micrograph of the needle-shaped crystals in Figure 13 with an optical image processing computer program to measure the electron microscope (ELMI) particle size distribution of the needle length, which is also shown in Figure 13. The ELMI particle size distribution is not very accurate, because we counted only 991 particles and it was very difficult to distinguish between neighboring particles. Nevertheless the AUC particle size distribution agreed reasonably well with the ELMI particle size distribution. The ELMI particle size would be expected to be higher, because the needle length (ELMI) is being compared with the equivalent sphere diameter (AUC).

Figure 14 shows another example with nonspherical particles. Instead of being dispersed in water, the heavy ($\rho = 4.2\,\mathrm{g\,cm^{-3}}$) Mn/Zn ferrite nanoparticles were dispersed in the organic solvent triethylene glycol (TEG).

Figure 14 AUC particle size distribution of Mn/Zn ferrite particles in a magnetic fluid, dispersed in triethylene glycol, concentration $1\,\mathrm{g\,L^{-1}}$. (Reproduced from Mächtle[11] by permission of Biophysical Society.)

The dispersion is a magnetic fluid which is switchable in a magnetic field, and it may perhaps be used in the near future in coupling devices, seals and dampers. Our task was to study the agglomeration of the primary 20-nm particles under different conditions. In the special case shown in Figure 14, it was found that the dispersion consisted of 20% w/w of primary 20-nm particles and 80% w/w of highly agglomerated particles with diameters between 40 and 400 nm.

Figure 15 shows an example of historical importance, the original sample of Rinde and Svedberg:[3] pure colloidal gold particles with a very high density of $\rho = 19.3\,\mathrm{g\,cm^{-3}}$ (and a complex refractive index $n(\mathrm{Au}) = 0.706 + i \cdot 2.42$ at $\lambda = 546\,\mathrm{nm}$ and $T = 25\,^{\circ}\mathrm{C}$, which we use for the Mie theory). These gold particles have an extremely small diameter ($D = 5$ to 50 nm), which demonstrates the lower measuring limit for particle diameters of the AUC particle size distribution method with a light scattering/turbidity detector. The gold nanoparticles themselves are embedded in a transparent film of polyvinylpyrrolidone, as the electron micrograph in Figure 15 shows. For the AUC particle size distribution measurement we simply dissolved this film in water. There is a reasonable agreement between the ELMI and AUC results. The film itself has been tested as a fast nonlinear optics switch for optical computers.

Figure 16, our last example, demonstrates that the AUC particle size distribution method works very well with emulsions, including liquid nanodroplets.

We prepared an aqueous 10% w/w emulsion of two monomers by mixing 50% w/w styrene and 50% w/w stearyl acrylate, stirring them with an Ultra Turrax™ mixer and applying ultrasound. We describe this emulsion as a mini-emulsion, because the diameters of the monomer droplets are about 100–500 nm, as the AUC particle size distribution in Figure 16 shows. This mini-emulsion remains stable for 2 weeks, because the hydrophobic stearyl acrylate acts as a cosurfactant. We measured the density of these liquid droplets by H_2O/D_2O analysis, and obtained a result of $\rho = 0.882\,\mathrm{g\,cm^{-3}}$. We polymerized the droplets by increasing the temperature and adding a water-soluble initiator. We then again measured the particle density of the resulting polymer dispersion by H_2O/D_2O analysis, and obtained a result of $\rho = 0.984\,\mathrm{g\,cm^{-3}}$. The AUC particle size distribution is also shown in Figure 16. As expected, the droplet/particle density increased due to polymerization, but the particle size distributions of the monomer droplet emulsion and the polymer latex particles are identical.

8 OUTLOOK – THE NEW TWO-LASER-BEAM TECHNIQUE AND VERY SMALL (1–20 nm) PARTICLES

This section deals with two current topics. Firstly, how is it possible to increase the precision and resolution of the AUC particle size distribution method with the light scattering/turbidity detector for particles with a diameter of 10–5000 nm? Secondly, how can we measure extremely small particles (1–20 nm) which scatter hardly any light and cause hardly any turbidity?

The experimental set-up with one (laser) light beam, described in Figure 2, may offer a solution to the first problem, but it has three disadvantages:

1. It is not always possible to fill the measuring cell up to exactly the same height, because small air bubbles with different sizes are formed during the

filling process. This results in an error Δr_M in the radius of meniscus r_M (see Figure 4) and, according to Stokes' law, the particle diameter D as well. Thus if we could reduce Δr_M we could reduce the error in D too.

2. Because we never know if the particles of an unknown dispersion will form a sediment or float to the surface, we position the laser beam in the middle of the cell between the radius of the meniscus r_M and radius of the base r_B. Thus we always use only the half of the maximum possible running distance $(r_B - r_M)$ of the particles. Increasing the running distance would also increase the range of diameters which can be measured.
3. In H_2O/D_2O analysis, we always need a third cell with the dispersion medium 50% H_2O : 50% D_2O to allow the computer to recognize whether the unknown dispersion particles form a sediment or float to the surface, i.e. whether we have to use r_M or r_B in our calculations, according to Stokes' law in Figure 4. If we did not need to use this third cell, we could run three H_2O/D_2O analyses simultaneously in an eight-cell rotor instead of only two.

To circumvent these three disadvantages of the set-up shown in Figure 2, we have devised a new set-up, shown in Figure 17 by introducing a second parallel measuring beam.

We can change the radial position of the two laser beams, the inner and outer positions r_1 and r_2, continuously between r_M and r_B. It is still not clear what their optimum position is. The preliminary measurements presented in Figure 18 were made at two different positions, at one-third and two-thirds of the way along the distance $r_B - r_M$.

The right side of Figure 17 shows a measurement performed on a monodisperse latex. The two simultaneously measured $I(t)$ fractionation curves are steep one-step curves. Both of them and – very importantly as a third possibility – the *difference* between them deliver the particle size distribution of the measured latex according to Stokes and Mie, if the particle density and the refractive index are homogeneous and known. The computer calculates which of the three particle size distributions is the best one. If the particles form a sediment (and if r_M is precisely known) the outer particle size distribution is the best one. If the particles float to the surface ($\rho_P < \rho_{DM}$) the inner particle size distribution is best. If r_M is not precisely known (because of air bubbles of different size or a small leakage in the cell) the difference between the inner and outer curves gives the best particle size distribution because we do not need to know the value for r_M to be able to calculate it. Instead, we need to know the value for the new "running distance" $(r_2 - r_1)$, which has to be measured once only and is then constant for all cells and every new run. Figure 18 shows an example of a measurement made with this new two-laser-beam set-up.

The insert in Figure 18 shows the two simultaneously measured $I(t)$ curves (and the exponentially increasing rotor-speed curve $N(t)$) for a 1 : 1 : 1 mixture of three monodisperse polystyrene calibration latices with known diameters of 120, 550 and 1300 nm. These two $I(t)$ curves and the difference between them, $I(t)_{inner} - I(t)_{outer}$,

Figure 17 Schematic diagram of a two-laser-beam set-up in an ultracentrifuge used to measure particle size distribution. (Reproduced from Mächtle[11] by permission of Biophysical Society.)

Figure 18 Three AUC particle size distribution curves of a mixture of three monodisperse polystyrene calibration latices (120 : 550 : 1300 nm (1 : 1 : 1 wt. parts), calculated from the two $I(t)$ curves shown in the insert and from the difference between the curves for $I(t)_{\text{inner}} - I(t)_{\text{outer}}$. (Reproduced from Mächtle[11] by permission of Biophysical Society.)

can be transformed according to Stokes and Mie into the three particle size distribution curves shown in Figure 18 (the differential particle size distribution is shown alongside the integral particle size distribution). There is fairly good agreement between these three particle size distribution curves. The mixing ratio and the diameters are reproduced to within ±5%.

There are some small differences between the three particle size distribution curves, but we will not discuss them here because these are the very first measurements that we have made with our new two-laser-beam set-up. These issues will be discussed in a forthcoming paper. However, there is evidence to suggest that the difference between the curves gives the most precise particle size distribution and also the highest resolution. The main lesson to be learnt here is that Figure 18 demonstrates that our new concept actually does work.

It can always be seen from the two $I(t)$ curves (as shown in the insert of Figure 18) whether sedimentation or flotation takes place within the latex. If the running time of the particles in the outer beam t_{outer} is higher than in the inner beam t_{inner}, the latex forms a sediment. If $t_{\text{inner}} > t_{\text{outer}}$ is valid, the latex particles float to the cell meniscus. This behavior can be distinguished very easily by a computer. This is important for the H_2O/D_2O sedimentation analysis, because it can then be performed without the 50 : 50 H_2O/D_2O mixture.

The answer to the second problem is simple: we have to use other detectors for nonturbid, very small (1–20 nm) particles instead of light scattering/turbidity detectors. We need to use refractive index detectors (schlieren or interference optics) or UV-absorption detectors, as in the case of dissolved molecules with high and low molar masses. Mächtle[13] presents an example of a measurement made of 5–25 nm SiO_2 particles, performed with the famous old Model E AUC device from Beckman fitted with schlieren optics. The best example[12] in the literature of this aspect of inorganic colloids, performed with the latest AUC instrument (the OPTIMA-XL-IA from Beckman, which has a 180–900 nm UV scanner and interference optics), is presented in Figure 19. It shows the AUC particle size distribution of extremely small (0.4–2.0 nm) particles of colloidal platinum (aqueous sol, $\rho_{\text{Pt}} = 24.45\,\text{g cm}^{-3}$) in angstrom resolution performed with the UV scanner at $\lambda = 380$ nm, at 25 °C and maximum constant rotor speed of 60 000 rpm. The resolution is nearly atomic. Figure 19(a) shows different radial UV scans at intervals of 2 min. The bold line is transformed by Stokes' law into the particle size distribution in Figure 19(b). Different scans yield nearly the same particle size distribution (if they are not too early or too late), indicating that diffusion effects do not have a disruptive effect. We believe that inorganic colloidal (1–20 nm) particles of this type will play an important role in the near future in metal sols, semiconductors and nonlinear optics. AUC makes it possible to study their growth mechanisms.[12]
